**Catastrophe
theory and caustics**

**Accelerators
or the future**

DEAE-Sephарose® CL-6B **CM-Sephарose® CL-6B**

**Macroporous, bead-formed ion exchangers
based on the new high-stability, cross-linked
agarose matrix, Sepharose CL**

- High resolution and capacity for high molecular weight proteins and other biopolymers
- Exceptionally stable bed volume. Excellent flow rates
- Can be used in polar organic solvents and in solutions of non-ionic detergents
- Can be sterilized repeatedly by autoclaving
- Rapid equilibration. No precycling

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (*a*) is preferred to *e^a* if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

- (i) only one reference number need be used if the reference is to several papers by identical authors,
- (ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

Melanotropin-daunomycin conjugate shows receptor-mediated cytotoxicity in cultured murine melanoma cells	J. M. Varga, N. Asato, S. Lande and A. B. Lerner	56

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (*a*) is preferred to *e^a* if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

Unmasking of thromboxane A ₂ synthesis by ureteral obstruction in the rabbit kidney	A. R. Morrison, K. Nishikawa and P. Needleman	259
Is yawning a cholinergic response?	R. Urbá-Holmgren, R. M. González and B. Holmgren	261
Myasthenia gravis serum reduces acetylcholine sensitivity in cultured rat myotubes	R. Anwyl, S. M. Appel and T. Narahashi	262
Human myasthenic sera reduce acetylcholine sensitivity of human muscle cells in tissue culture	S. Bevan, R. W. Kullberg and S. F. Heinemann	263
Long term β -adrenergic blockade reduces tyrosine hydroxylase and dopamine β -hydroxylase activities in sympathetic ganglia	A. E. G. Raine and I. W. Chubb	265
β Endorphin inhibits ACh turnover in nuclei of rat brain	F. Moroni, D. L. Cheney and E. Costa	267
Calcium-dependent presynaptic action of substance P at the frog neuromuscular junction	A. Steinacker	268
Postsynaptic receptors are not essential for dopaminergic feedback regulation	G. Di Chiara, M. L. Porceddu, W. Fratta and G. L. Gessa	270
Hydroxyproline-containing protein adsorbed on to cellular elements of whole human blood	R. Miller, M. B. Engel and H. R. Catchpole	272
Effect of a single amino acid substitution on stability of conformation of a protein	K. Yutani, K. Ogasahara, Y. Sugino and A. Matsushiro	274
Preponderance of synonymous changes as evidence for the neutral theory of molecular evolution	M. Kimura	275
Inheritance of recombinant HLA-GLO haplotype suggesting the gene sequence	N. L. Reinsmoen, P. S. Friend, W. V. Miller, A. Burgdorf, E. R. Giblett and E. J. Yunis	276
Structure-function relationship of 5' non-coding sequence of rabbit α - and β -globin mRNA	F. E. Baralle	279
A new pathway for DNA repair in <i>Escherichia coli</i>	L. Samson and J. Cairns	281
Wide ranging plasmid bearing the <i>Pseudomonas aeruginosa</i> tryptophan synthase genes	R. W. Hedges, A. E. Jacob and I. P. Crawford	283
Phonons and the elastic moduli of collagen and muscle	R. Harley, D. James, A. Miller and J. W. White	285
Crystal structure of anhydrous cholesterol	H. S. Shieh, L. G. Hoard and C. E. Nordman	287
Direct evidence for an interaction of β -adrenergic blockers with the 5-HT receptor	D. N. Middlemiss, L. Blakeborough and S. R. Leather	289

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

MSA and EGF receptors on sarcoma virus transformed cells and human fibrosarcoma cells in culture	G. J. Todaro, J. E. De Larco, S. P. Nissley and M. M. Rechler	526

Electrical responses of <i>Stomatoca atra</i> induced by an extract of <i>Aequorea aequorea</i>	W. E. Schwab	701
Bivalent-cation-stimulated ATPase activity at preformed exocytosis sites in <i>Paramecium</i> coincides with membrane-intercalated particle aggregates	H. Plattner, K. Reichel and H. Matt	702
Transition probability and the origin of variation in the cell cycle	R. Shields	704
Hybrid cell lines with T-cell characteristics	R. A. Goldsby, B. A. Osborne, E. Simpson and L. A. Herzenberg	707
The adjuvant active fraction of delipidated mycobacteria	I. J. Hiu	708
IgM-IgG switch-over among antibody-forming cells in the mouse	C. Bleux, M. Ventura and P. Liacopoulos	709

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; $\exp(a)$ is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors,

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

Simple model for self and non-self-discrimination in invertebrates	C. R. Parish	711
Succinyl bee venom melittin is a leukocyte chemotactic factor	P. C. Wilkinson	713
Theophylline-induced changes in ion transport and conductance in human small intestinal mucosa	C. L. Corbett, P. E. T. Isaacs, P. C. Hawker and L. A. Turnberg	714
Fast motor units are not preferentially activated in rapid voluntary contractions in man	J. E. Desmedt and E. Godaux	717
TEA binding sites in crayfish axon membranes	F. Hucho	719
Pentylentetrazol and penicillin are selective antagonists of GABA-mediated postsynaptic inhibition in cultured mammalian neurones	R. L. Macdonald and J. L. Barker	720
Reactivation of murine cytomegalovirus by cyclophosphamide	D. R. Mayo, J. A. Armstrong and M. Ho	721
Virus protein p30 in blood predicts development of leukaemia in mice injected with MuLV	K. Ulrich and B. A. Nexø	723
Histone content of germinating pea embryo chromatin decreases as DNA replicates	F. Grellet, M. Delseny and Y. Guittou	724

'Nation shall speak peace unto nation'... at -30 dB

How should television develop in the next ten or twenty years? On the technical side, it goes without saying that most people would like to see every economically visible development explored: cable television, satellite broadcasts, use of the receiver for access to news, data and computers, new types of television screen and so on. But on the question of programming there would be a variety of answers, as the recent Annan Committee has found in trying to formulate recommendations on Britain's fourth channel. Some want more of the same, some want education programmes, some argue that more inevitably means more. There is little doubt, however, that most (and this not likely to be just a British view) would like more choice if there were some guarantee that this did not mean rationing of resources. One fascinating way in which this could have been achieved by enabling viewers to tune into other countries' programmes is likely to be suppressed before the general public is even aware of the possibilities.

At present, of course, television reception in the hundreds of MHz range is restricted by line of sight. The technology for transmission in the 11.7 to 12.5 GHz band from geostationary satellites is advancing rapidly, however, and there is talk in some countries of satellite broadcasting within fifteen to twenty years. At the same time, pressure is growing, but not in every country, for the allocation of frequencies in the same band to terrestrial services. An internationally agreed decision in 1971 gave priority to satellite broadcasting in choice of channels and this has meant a global gathering at Geneva earlier this year to allocate channels long before the precise needs can be foreseen. And since land-based services will develop well ahead of satellite broadcasting, the latter, now allotted its channels, will find itself in a straitjacket. The 20 MHz bands can certainly be used for radio as well as television, but a large screen digital receiver, which some describe as the television of the future, might well need greater bandwidth. It is not the technological straitjacket, however, which is most disturbing—it is the political constraint that programmes are not to cross frontiers.

As envisaged at present, each broadcasting nation would have its own satellite which would be at liberty to transmit on up to five channels, at 80 MHz spacings. The beams from satellite antennas would have a minimum width of 0.6° (which would more than cover Ireland) and could be elliptical (a beam $1.8^\circ \times 0.7^\circ$ would cover the UK). Every country in Europe, including Luxembourg, the Vatican, Andorra, Monaco, Liechtenstein and San Marino, has been solemnly awarded its five channels; in the case of the

smaller countries (in which there is arguably not quite enough talent to provide five simultaneous programmes and equally arguably adequate line-of-sight to surface transmitters), if they chose to launch a satellite the smallest beam possible would provide neighbouring countries with ample, if accidental exposure. On the other hand countries that wish to use one or more channels for deliberate broadcasting beyond their frontiers with broader-than-necessary beams have to obtain prior agreement from countries they wish to serve. The Scandinavian countries have been able to come to such an agreement, and the Vatican, Tunisia and Saudi Arabia (to serve Islamic countries) have also been allocated 'superbeams'. But other requests were turned down. Ireland wished to cover the UK for the sake of the large Irish population, but the UK claimed they had not had enough notice. And none of the major countries at the meeting seem to have made any public noises about broadcasting general television programmes over a wide area; indeed it is fairly widely known that the Eastern Europeans and France would refuse permission for such an invasion of their domestic life.

The objections are fairly obvious.

- Television could deliver some pretty slick propaganda; indeed it could, but the public on the whole switches propaganda off, and in any case an international channel might sensibly be compiled only of material which is also being shown domestically.
- There are technical problems of channel assignment and of having to direct an antenna at more than one satellite; hardly crippling problems in a technological age.
- The whole thing would only appeal to a tiny minority; well you wouldn't have to buy a multidirectional aerial if you didn't want to, and who is sure that foreign sport, music, entertainment and documentaries would not catch on? Twenty years ago Indian food and Spanish holidays were only for a tiny minority.
- We can already see foreign programmes; yes what 'the authorities' decide to accept on our behalf.

Too many conflicts in the past and too many prejudices in the present are based on the caricatures that most nations have of fellow-nations—caricatures largely fed by editorial control of the media. Here would have been a marvellous opportunity to ensure that at least the next generation could learn a lot more about the world as a whole—and maybe be stimulated to learn more foreign languages. But it has been thrown away. The next round of frequency discussions is probably ten or fifteen years in the future and will be too late. □

Europe's pollution politics

Chris Sherwell reviews some of the problems in producing an EEC environment policy

THE achievements of international organisations are, in large measure, a political trade-off between what is theoretically desirable and what is practically possible. Unsurprisingly, the balance is usually in favour of the latter. In spite of, and perhaps because of their unique but complicating commitment to political and economic union, the nine member countries of the European Community (EEC) display the attribute more than most organisations. Nowhere is this more amply demonstrated than in environmental policy.

The EEC's very involvement in the field is under challenge. When the European Commission last year produced its Second Action Programme on the Environment, covering the years 1977 to 1981, one of the most powerful of the environmental lobbies, the European Environmental Bureau (EEB), representing some 38 organisations throughout the Nine, weighed in with a powerful critique. There was a contradiction, it contended, between the main goal of the EEC, which was continuous and balanced economic expansion, and the basic principle of ecology, which was a dynamic equilibrium.

In fact the EEB displays all the signs of being pleased with the EEC involvement in environmental matters. The second action programme, after all, reads much like an environmentalist's manifesto, so breathtaking is its broad sweep. The EEB's reservations concern the precise character of that involvement. It criticises, perhaps with some justification given the programme's breadth, the curious lack of attention given to transport, population growth, regional policy and national programmes. This sort of gap, it is intimated, begs its own questions and reinforces the contradictions.

Questions are indeed necessary.

Environmental issues find under an office in the Commission with split responsibilities—the Environment and Consumer Protection Service. Its staff numbers around 100. Environmental groups would like to see greater status attached to the department, perhaps making it a Directorate General. More important and perhaps contradictorily, they would like to see its work better integrated in the activities of the Commission and Community as a whole.

The argument is that the EEC's involvement in the environment will be ineffective if it is limited to drawing up a programme regardless of what the various departments of the Commission are doing, as now seems to happen. The aim ought to be to promote the concept of environmental quality in all the departments, so that the work done by an environment department is not emasculated by the activities of other departments. An environment protection department, in short, ought to participate in the policy making of other departments.

In spite of this very real structural problem facing the Commission, there are people who will praise its work; they recognise the constraints, both manpower and financial, that it faces in trying to coordinate the activities of nine countries across a broad range of environmental and other matters. But its achievements in such adversity are in turn the spring of other equally penetrating criticisms of the environment policy it administers. These emphasise the need for selectivity as a paramount requirement for success. The argument is that the lack of focus, the effort to do "too much too soon" and "run before being able to walk", is a fundamental cause for disillusion.

A glance at the second action programme is certainly enough to convince

even the most ambitious lobbyist that the chances of it being legislated in fifteen years, let alone five, are at best remote. This means that the sense of priority can become blurred, and emphasises the need for greater clarity about what the Community can do and what its role can be. After all, it is not just the Commission whose institutions may need modifying to encourage a well-rounded environment policy; it is also the Council of Ministers, before which the issues may come somewhat haphazardly and which finds the greatest difficulty in dealing with them systematically and without awkward and embarrassing haggling. The point is, not all environmental matters demand a specifically European approach.

Techniques of control

If the question of the degree to which the Community should become at all involved in environment policy seems important, it does not exhaust the list of fundamental questions on the subject which it currently faces. The very techniques of control are another issue, and form the basis for the longest running political controversy of all in this area.

Even boiled down, the essentials of the European debate are far from straightforward. The environment is recognised as having some capacity to receive pollutants. Where risks are apparent but complete prohibition is unnecessary, controls are needed. Two forms come under scrutiny, known in Europe as 'quality standards' and 'quality objectives'. Put most simply, quality objectives are pollution levels which the nine member states each undertake to do their best to attain, and quality standards are levels which the nine states each become obliged to achieve. The debate is about how precisely to use them.

Going by the political argument as it has developed thus far, the difference looks more than merely legalistic. For, having painstakingly arrived at a view of what the standards or objectives should be, the Commission is able to take steps to assist in their attainment by establishing what in its jargon are called 'norms'. This, it seems, is where the trouble starts, because it has meant the introduction of the notion of emission standards, to which Britain has strongly objected and other states and the Commission have given support.

The characteristic of emission standards causing Britain to dig its feet in is not that they are to be used, but that they are to be used uniformly. Britain has supported quality objectives on the grounds that they can take account of the varying nature of the receiving environment in a way that standards, because of their intrinsic

uniformity in the Community, cannot. To Britain, quality objectives imply emission standards but not uniform emission standards. Once it is agreed what quality a particular stretch of water, say, ought to have (which in turn depends on the use to which it is put), a quality objective must be set. To reach this, emission standards will need to be set for particular polluters on that stretch of water, but they will be peculiar to that stretch of water being used for that purpose.

Not so, say the hard-line Europeans. The imperfections of quality control mean that the only reliable path to reductions in pollution is to declare emission standards for particular classes or sections of industry and apply them uniformly throughout Europe; such standards would have to be achieved by a certain time. The British version of an emission standard, they say, is effectively a licence to pollute.

The arguments have in fact found their most coherent expression in the debate over aquatic pollution, itself just one aspect of pollution generally and a mere fragment of the environment question. Pointing to its shorter rivers, larger coastline and smaller and lower concentration of factories, Britain has argued that it can have pure water without adopting on a uniform basis the higher emission standards that would be demanded on mainland Europe. Other countries, with an eye to the Community's competition policy, have said this would give Britain an unfair competitive advantage in international trade and jeopardise a common policy both in competition and environment matters. Britain has contended that its advantage derives from possession of a natural resource and that a uniform policy would be wasteful, only harmonising costs rather than encouraging fair competition.

This dispute has occupied a considerable amount of important time. In part this is no doubt because of misunderstandings. For example, at a seminar organised in London recently on EEC environment policy, one Commission official cited the hypothetical example of two states in exactly similar circumstances trying to achieve the same air quality, in one instance by tackling only a few big companies and in the other by tackling many small companies; this, he said, would amount to an unacceptable distortion of competition. A surprised British official found that the example fitted with his own country's view of having the same environmental responsibilities in the same circumstances.

Much of the debate as it has involved aquatic pollution has necessarily involved the so-called 'black list' and 'grey list' of dangerous substances,

classified on the basis of toxicity, persistence and accumulation. Put most simply, the idea is to isolate black list substances from the environment to the point where there can be no doubt that they will harm human health, but some countries have said that black list substances should not be dumped or discharged at all. Others doubt the need for this, given the uncertainty about the substances themselves and about the absorptive capacities of the environment.

Although the fundamentals of the argument remain essentially unresolved, a breakthrough did come at a meeting of the Council of Ministers in December 1975 when a compromise solution was reached on black list substances. This embraced a dual approach allowing either emission standards on a uniform Community basis, or quality objectives which catered for different circumstances. Formally the compromise retained the notion of uniformity and allowed temporary exemptions for which Community but not uniform standards could be used: the exceptions would arise when a member state could prove that quality tests were being maintained throughout the particular area concerned, and would be re-examined every few years; the whole system would become operational within about three years by which time priorities would be decided and actual objectives and standards set. Even then it might take five or ten years to achieve, and in light of this Britain views the application of the quality objectives as unlikely to lag much behind the implementation of emission standards.

For the grey list it was agreed that individual member states would prepare programmes which included quality objectives, from which they would derive emission standards of their own. The Commission would ensure that comparisons between countries were made to ensure some uniformity of approach, but the underlying approach became one involving quality objectives, and there is no mention of emission standards on a uniform Community basis. The recent seminar in London may anticipate an even broader acceptance of the British view.

Fears persist that the black list will in effect become a grey list. However, the detail of the breakthrough, though important, was less important than its immediate consequences. Progress could be made in April 1976 towards a Rhine convention covering pollution by salts, chemical pollution, thermal pollution and pollution by radioactivity. Agreement on limits of chemical pollution was soon reached, and a month later ministers met again to resolve

differences over salt pollution. Progress was also possible on the matter of Mediterranean pollution. In Barcelona in February 1976 16 countries finalised details of a framework convention and two protocols covering the discharge of petroleum waste and the tipping by ships and aircraft of black list and grey list pollutants into the Mediterranean.

Achievements not matched

These 'international' achievements involving Community members have not since been matched within the Community itself. At the most recent Council of Ministers meeting last December, for example, four draft directives from the Commission awaited approval: on the biological surveillance of the population for lead in the blood; on the quality of water intended for human consumption; on the waste from the titanium dioxide industry; and the reduction of water pollution by paper pulp plants. The Council adopted only the first of these.

At the end of last year, in fact, there was still around a dozen sets of proposals for directives sitting on the Council's desk awaiting action. They included proposals relating to the lead content of petrol (submitted 7 December 1973), the dumping of wastes at sea (submitted 12 January 1976), health protection standards for sulphur dioxide and suspended particulate matter in urban atmospheres (submitted 25 February 1976) and toxic and dangerous wastes (submitted 28 July 1976). Proposals for decisions awaiting adoption included one on the subject of organic micro-pollutants in water and another on exchanging information on the quality of surface fresh water in the Community.

This last item is expected to appear on the agenda, along with the other undecided items from the December meeting, when the Council of Ministers meets in June for the one and only time during Britain's present chairmanship. Outstanding items will probably also be included, and perhaps some new ones like the conservation of birds, though the chances of them being considered remain as always subject to the will of the member states on the higher

Keystone

priority items.

In its programme for 1977, published in February, the Commission says it will concentrate on four basic 'priority themes': measures to combat water pollution; evaluation of measures to prevent the deterioration of the environment; an anti-waste campaign based on a policy to encourage materials recycling; and implementation of the international conventions on the Rhine and the Mediterranean. It says it will therefore send to the Council proposals for directives on, amongst other things, protection of underground water, the quality of water for agricultural use, notification of industrial

activity involving dangerous substances (a lesson of Seveso), discharge of various particularly harmful pollutants, and on anti-noise measures.

The Commission remains optimistic. Its work goes ahead under the auspices of the second action programme, which the Council meeting of last December unanimously approved, adding the undertaking that it would act on concrete proposals from the Commission within nine months of them being forwarded. It may prove to be a tall order, given the fundamental character of some of the issues still outstanding concerning the Community's environment problem. But the

Community and its policies are nothing if not resilient. And the large number of directives which have already gone through suggest that the whole effort in the environmental field may have acquired a momentum.

That should allow some attack in the primary field of preventing and eliminating pollution and nuisances, where most attention has been concentrated. But managing the use of natural resources properly, controlling the ecological balance and economic growth, and generally protecting the biosphere—also aims of the EEC's second action programme—will plainly take a little longer. □

Spreading the word

David Spurgeon, recently in Asia, examines the growth of science writing there

THE business of writing about science for the mass media must have its ups and downs like any other business. Although it is difficult to judge without the evidence of a full-scale survey, it seems the trend in North America in recent years has been predominantly down. Editors no longer show the enthusiasm for science subjects that they did during the early post-Sputnik days and discussions have appeared in science writers' newsletters about the parlous state of their craft.

Some link the decline in interest to the scepticism—and in some measure, disillusionment—about the promise of science that followed the excesses of publicity associated with the US manned space programme, the development of nuclear power and 'wonder drugs' and other achievements. It seems a reasonable thesis; the earlier 'gee-whizz' phase of science writing was followed not only by a much more critical and judgmental phase, but also by the birth of various anti-science movements and by 'consumerism' and 'environmentalism'.

An interesting contrast is found in the Third World, particularly in Asia, where (again to some extent subjectively) interest in science journalism seems definitely on the upswing. Mack Laing, a Canadian science writer and professor of journalism, writing in *Depthnews Science Service*, a weekly newsfeature service of the Press Foundation of Asia (PFA), put it this way in a recent article from Manila:

There is a burst of activity in Asia these days toward achieving a greater public understanding of science. Some—perhaps even most—Asian nations are just waking up to the need for more public appreciation of how science and technology can help national development. Other countries

are going full blast on the same. Leaders in these countries argue that popularising science encourages people to understand and cooperate with government actions on large-scale problems such as conservation, pollution, irrigation and flooding by man-made reservoirs, sanitation and infectious diseases. They argue that interesting the youth of a country in science increases the country's science manpower and speeds national development. One way of bringing the word about science and technology to the people is through the media of mass communications.

The *Depthnews Science Service* and Mr Laing's activity in it are themselves interesting results of his newly-awakened interest. PFA, a non-profit agency founded by Asia journalists some ten years ago to improve the standards of the region's media, asked Canada's International Development Research Centre (IDRC) for funds to set up a science feature service within *Depthnews*. Its aim would be to set the pace for the Asian press in science coverage, which in its opinion (and that of other Asians) had been deficient until then. PFA also asked for an experienced science journalist from the West to set it up and train Asians in

the techniques of science journalism.

While it is too early to judge the commercial viability of the science feature service, the initial response of the Asian media has been surprisingly good. Mr Laing has found himself in the ironic position of having to admit that the interest shown by the media in Asia for his service's articles is much greater than he could imagine Canadian editors showing for a comparable service at home.

Among his chief sources of news in the Philippines are weekly news conferences set up specifically for science writers by the University of the Philippines and the National Science Development Board. The conferences were arranged to acquaint science writers with researchers whose work is sponsored jointly by these two organisations. It seems to be succeeding. At a recent conference, about ten media representatives gathered in a small room to hear a pharmacologist talk about work she and her colleagues had been doing in identifying plants with insecticidal qualities that could serve as replacements or alternatives for chemical pesticides. (The other subject, oddly enough, was music, but apparently this was atypical, almost all subjects being scientific).

To encourage attendance, the university has adopted the practice of paying the journalists to attend the con-

Sri Lanka seminar on popularising science, fiction writer Arthur Clarke speaking

ferences, which are held on Saturday mornings, and of giving them coffee and lunch. The sum is small (the equivalent of about \$9) and although the practice would obviously be unacceptable to the Western press, it may help (and perhaps be necessary) in the Philippines. Dr Joventino Soriano, the coordinator, first introduced the news conferences by holding a four-day science writers' seminar at a mountain-top retreat some miles from Manila. A travelling seminar was also planned in April, when media writers and researchers were to visit villages in three provinces north of Manila to see how science and technology can aid rural areas.

Similar seminars have been held by other organisations. In 1974, the IDRC held one near Manila for science writers. The response was strong from the media in eight regional countries, some of which already had science writers (and one, Korea, highly developed science coverage). In other countries (for example Indonesia) the interest was there but the media structure was not. In 1975, another seminar was held in India, with a similarly strong response from that country and others bordering it. A third seminar planned for June in Nairobi, will be for the East African media.

In March, a month-long Asian Training Course for Leaders in the Promotion of Public Understanding in Science, sponsored by UNESCO and the Science Foundation of the Philippines, was concluded in Manila. And in February, as a result of the previously mentioned India seminar, a meeting was held in Colombo, Sri Lanka, on 'Science writing for the people'.

In Sri Lanka, where science writing is largely ignored in English-language newspapers, possibly partly because newsprint shortages make for thin newspapers, the Ministry of Education is reported to be planning on providing scholarships for science writers to obtain university degrees.

At the recent seminar, Professor P. P. G. L. Siriwardene, the Vice-Chancellor of the University of Sri Lanka, said that science must be written in the vernacular to get to the people. But he added that popularisation of science has been "hamstrung by a lack of funds". In the developing countries, he said, science popularisation should be "an important national venture". The question of language is an important one, as delegates to the IDRC's first seminar noted. In many Asian and African languages there are no words for some scientific

concepts. However, in Sri Lanka, as in India, some science does appear in the vernacular-language press.

The Philippines is one of the most enthusiastic promoters of science popularisation among Asian countries. In addition to the emphasis on science news (which is perhaps attractive to editors because of government control of the country's press and the dearth of genuine news stories) there are hundreds of science clubs, which are joined in a federation and hold Youth Science Camps. Science campers visit rural areas to explain science and scientific concepts to farmers and remote villagers, and to replace superstition and myth by rational explanations of natural events. A science quiz, an annual high school contest, has attracted 8,530 regional participants and 292 national participants since 1969.

In a speech prepared for the course on public understanding held in Manila last March, President Marcos said:

We are belatedly finding out that the harnessing of science and technology is not a mere matter of learning formulae, but a process of cultural transformation itself. It is in this light that I perceive the importance of promoting wide public understanding of science, technology and the environment. □

RED SEA

Sifting the sediment

The staff of La Recherche reports on the prospect of mining sediment in the Red Sea

A CONTRACT was signed on 25 March, in Paris between the Red Sea Commission, represented by its secretary general, Dr Zaki Mustafa, and the Argas Company, represented by its president, Jamil Jawa. The contract, involving FF30 million (£1=FF8.54) is one of a series of agreements on the exploitation of the metalliferous sediment in the Red Sea, which contains 5.8% zinc, 0.90% copper and 110 g of silver for every ton of dry material as well as iron and manganese.

The first agreement between Saudi Arabia and the Sudan, signed in May 1975, was to cooperate in exploiting the mineral resources at the bottom of the Red Sea in the so called 'Common Zone', which lies between the two countries. The resulting Red Sea Commission, which has its headquarters at Jeddah, was founded to promote and encourage mining research and any means of exploiting the minerals in the zone. The Commission then called in the Argas Company (The Arabian Geophysics and Surveying Company, a joint

venture between the Saudi company Petromine and the French Compagnie Générale de Géophysique).

Two preliminary contracts in March and July 1976 (for FF 15 million and FF8 million respectively) covered geochemical, seismic and aeromagnetic studies. The work to be carried out under the third contract, the one recently signed, will analyse the environment including swell, currents, thermosalinity and biology to ascertain the effect of exploitation on the environment and to determine the conditions necessary for lowering a vertical tube for pumping mud to 2,200 m.

The metal extracted from the sediment would be treated on the spot, and mineral salts and tons of residue extracted from the metal ore would be thrown back into the sea; but what would become of this residue, and what effect it would have on the flora and fauna before settling back on the sea bed remain unanswered questions. A German company, Preussag, has meanwhile been developing the extraction process. A pilot preconcentration plant could be working by 1982, and it will not be known until then whether the project is feasible. Preussag is also under contract from the Red Sea Com-

mission, which is providing \$25 million for six years. The Commission has engaged the services of a French public body in charge of geological and mining research, the BRGM, to coordinate activities and act as technical adviser.

If the project succeeds, it will be the first time that marine sediment has been put to use: other companies engaged in working the ocean bottom are more interested in nodules. The sediment contains important components, however, especially copper, and similar deposits could be found in other parts of the world. Geological studies provide an explanation for the formation of mineral rich sediments: in the Red Sea, where rock outputs cut across the rift, there is a zone of intense volcanic and thermal activity, and the rocks give off large quantities of metallic salt into the water. In the presence of the hot brine frequently found in these regions the metallic salts are eventually precipitated. Thus a sedimentary bed is formed containing enough metal for it to be thought worth while mining out. The first mining will be in the Atlantis II fault, where it is estimated that there would be 850 million tons of sediment, that is 7×10^6 tons of copper. But at least 18 faults are known in the hot brine regions of the Red Sea; some probably do not contain sediment, but others could be extremely profitable. □

USA

Going public on rights

Colin Norman reports from Washington on an appeal in support of named scientists who are victims of political repression

In a significant departure from its usual style of quiet diplomacy, the National Academy of Sciences last week called a press conference to urge public support for eight scientists in three countries who are "victims of grave official harassment for political reasons". The action, taken by a newly-established Committee on Human Rights, signals that the Academy is prepared to adopt a more aggressive role in defending scientists against political repression than it has in the past.

The eight scientists involved in the appeal are five Argentinian physicists who disappeared in 1976, a Uruguayan mathematician arrested in October 1975, who has been charged with subversive activities and allegedly tortured, and two Soviet scientists, one of whom is serving a prison term and the other is under arrest awaiting trial. According to Robert W. Kates, the chairman of the Academy's Committee on Human Rights, these eight scientists are the first of "a large group" which the Academy hopes eventually to take public action on. "They are", said Kates, "at best symbolic of the many scientists who are subject to repression".

The Committee on Human rights was established a year ago, following complaints from some Academy members and from the Federation of American Scientists (FAS) that the Academy had been too timid in its attempts to defend scientists against acts of political repression. Though it made one highly publicised statement in support of Andrei Sakharov in 1973, the Academy has worked mostly behind the scenes, making private representations to officials of foreign governments on behalf of harassed scientists. Early last year, there was a move, sparked by complaints by the FAS Director, Jeremy J. Stone, to urge the Academy to back up its private negotiations with occasional public statements.

The Academy responded by establishing the Committee on Human Rights and it also adopted a set of guidelines which suggested that the Academy would speak out publicly when the occasion so demands. It seems from last week's press conference that such public appeals may become more common. Kates said that the committee will concentrate on in-

dividual cases rather than making broad statements of principle, and he indicated that several more cases will be added to the list as soon as further evidence is collected. "This is just the beginning", he said.

Asked whether the committee would be prepared to urge the Academy to take further steps if the appeal has no effect, Kates said that the committee would proceed one step at a time. The ultimate sanction available to the Academy would be to back out of an exchange agreement with a country which persists in acts of political repression against scientists. In any case, there seems to be a strong body of opinion within the Academy supporting the committee's moves so far. Kates said last week that a letter sent to Academy members asking for their support in writing to foreign officials to protest acts of political repression produced 258 positive responses.

The specific action taken last week was to ask scientists to write to officials in Argentina, Uruguay and the Soviet Union in support of the eight scientists.

In Argentina, the five physicists are Federico Alvarez Rojas, Gabriela Carabelli, Juan Carlos Gallardo, Antonio Misetich, and Eduardo Pasquini. All disappeared during 1976, presumably arrested, but the government claims to have no knowledge of them. The Academy is asking that they be permitted to see their families and that scientists be allowed to visit them to determine their state of health. In addition, the Academy is calling for the physicists either to be charged or released and that observers be permitted at any trial. In fact, however, members of the Academy's committee said that there is no guarantee that the five are even alive.

The Uruguayan mathematician, José Luis Massera, was arrested in October 1975, held incommunicado for a year and is now being tried in camera on charges of "subversive association". According to Lipman Bers, a member of the Academy's human rights committee, Massera, who is 62, is "the most distinguished mathematician in Uruguay" and he has a worldwide reputation. An avowed Communist, Massera has been "subject to severe torture", Bers said. In this case, the Academy is again asking for permission for Massera's family members and representatives of the world community of scientists to visit the mathematician, for observers to be permitted at his trial, and for him to be given access to books and other scientific material.

The two Soviet scientists are Sergei Kovalev, a biologist who is now serving seven years' hard labour and three years' exile for alleged activities against the Soviet state, and Yuriy Orlov, a physicist who was arrested in February 1977 and is awaiting trial on as yet unspecified charges. In Kovalev's case, the Academy is concerned about his ill health, and is appealing for commutation of his sentence to the time already served. The Academy is also requesting scientists to appeal directly to the Soviet authorities on Kovalev's behalf and to provide Kovalev himself "with every feasible manner of moral and professional support". As for Orlov, he has been a leading participant in the Soviet human rights movement associated with Sakharov, and was arrested as part of the recent crackdown on the dissident movement. The Academy is inquiring about his legal status and place of detention through a letter sent last week to the Soviet Ambassador in Washington, Anatoliy Dobrynin, and the human rights committee will "take appropriate action".

The Academy's new, more aggressive policy puts it in marked contrast to the Royal Society. In a speech to Royal Society Fellows last November, Lord Todd, the Society's President, expressed concern about the widespread political repression of scientists in many countries and about more subtle infringements of scientific freedom, but he said that the Royal Society should steer clear of making public pronouncements on the matter. Instead, Todd said that Royal Society officials would continue to make private representations on behalf of scientists whose human rights are being infringed.

Further details of the individual cases raised by the Academy last week, and addresses of government officials to whom correspondence should be addressed, can be obtained from the Committee on Human Rights, National Academy of Sciences, 2101 Constitution Avenue NW, Washington DC 20428. □

Sergei Kovalev

USSR

● The raising of quality standards is a major watchword of the current Five-Year Plan and a slogan for the forthcoming celebrations of the Diamond Jubilee of the Soviet Union. In the traditional panegyric of Soviet achievements given on Lenin's birthday (22 April), Mikhail Zimyanin, Secretary of the Central Committee of the Communist Party of the Soviet Union, noted among other achievements an improvement in the quality and efficiency of research and the coordinated study and solution of problems of scientific and technological progress. A major re-equipping of industry is under way, he said, and in spite of "difficult weather conditions" the last year has been marked by "new outstanding achievements of the Leninist agricultural policy of the Party".

Nevertheless, in at least some of the Union Republics, there is less emphasis on the implementation of the plans. In Lithuania, according to the First Secretary of the Central Committee of the Lithuanian Communist Party, there is a tendency for certain ministries and departments to draw up "easy" plans and adjust the targets downwards. The First Secretary of the Central Committee of the Byelorussian Communist Party, speaking at the recent Plenum, told a somewhat similar story. Some bodies including research institutes and the state statistical organs, he alleged, keep up a front of activity, busying themselves with data-gathering and the preparation of summaries rather than with the "scientifically substantiated recommendations" which the economy requires; even when recommendations were made, the proper experimental basis might be lacking.

He cited in particular a new system of product quality control for dairy farms which was recently worked out by the Byelorussian Scientific Research Institute of Agricultural Economics and Organisation and which has been widely publicised. However, the whole experimental basis of the scheme apparently rests on "a brief experiment on only one farm", reflecting a lack of practical trials reminiscent of the extremely scanty foundation for Lysenko's "vernalisation" scheme. Although not criticising in so many words the system of targets which is the basis of Soviet planning, the Byelorussian first secretary deplored the tendency to set targets without proper evaluation of the "qualitative parameters of economic development".

● The Dubna Joint Institute for

Nuclear Research has completed a cycle of experiments on the synthesis of element 107 by bombarding ^{209}Bi with nuclei of ^{54}Cr . The first experiments, in 1975, gave strong evidence of the formation of the element with a half-life of 2 milliseconds. The Dubna team, under Academician Georgii Flerov, has already syn-

thesised elements 103–106. In announcing the successful conclusion of the current series of tests, Academician Flerov gave a strong hint that they now would be aiming at elements of even higher atomic numbers—a new unit is being built, he said, which will increase the efficiency of nuclear interactions by a factor of several hundred.

● One of the major features of recent Soviet work in the Antarctic has been the drilling of deep cores both through the ice-shelf and on the continent proper. A special electrothermal core drill is used, with a maximum penetration of 6 metres an hour with, when necessary, a special system for keeping the core sterile. All apparatus is easily transportable by sledge or helicopter, hence cores may be taken if required at a considerable distance from the base.

The ice-shelf project was based on the Novolazarevskaya station (Queen Maud Land). The purpose of the experiment was not simply to penetrate the ice but also to sample the sea-water and sea-bed below. The first such shafts gave the depth of water beneath the ice as 40 m, its salinity approximately that of the open ocean and its temperature -1.5°C to -1.9°C . The sea-bed specimens indicated that the composition of diatoms deposited had not

changed during the past 10,000 years.

Inland drilling operations were based on the Vostok station at the 'Pole of Cold', where the icecap is some 3,500 m thick. A 980 m core from this area has been analysed by the ^{18}O method. According to Professor Evgenii Korotkevich, who is one of the supervisors of this project, the core indicates a palaeo-climatic pattern with a mean annual temperature at 15,000 B.P. some 5° below the present figure, indicating a significant drop in the world temperature. This, he says, was followed by "rapid reconstruction" of the climate, thought to be associated with cosmic phenomena, with the present climatic conditions becoming established *circa* 11,000 B.P., since when the climate has remained virtually unchanged.

The Vostok station is also the base for taking sterile cores for experiments on the 'reanimation' of microorganisms. The cores from the twentieth expedition (Summer 1975–76) penetrated to 207 m, the most ancient organisms reanimated being from the 197 m level ($\sim 8,500$ B.P.). From the specimens of the twenty-second expedition (Summer 1976–77), it is hoped to establish the limit of survival of microorganisms in the anabiotic state, a topic, it is said, in which the Laboratory of Space Microbiology of the Microbiological Institute of the Soviet Academy of Sciences is showing considerable interest.

● The case of Anatolii Shcharanskii, at present under arrest pending investigation, is a peculiarly ironic example of the 'secrecy' issue which faces scientists wishing to emigrate to Israel. Shcharanskii, who is prominent both in Jewish refusenik circles and in the larger human rights movement (he is a member of the banned Helsinki monitoring group), studied at the Moscow Institute of Physics, specialising in computer science. He has not, however, ever worked at his profession.

Because the research post he was offered at the Physics Institute of the Academy of Sciences could conceivably have been considered as 'classified', thereby threatening his chances of emigration, he denied himself the possibility of creative work in his own field and was employed as an engineer. The latest Tass allegation that Shcharanskii has been organising the collection of classified information to send "abroad" thus adds a bitter twist to his story.

Vera Rich

IN BRIEF

Brain drain persists

Although the brain drain has been partially plugged by restrictive immigration regulations in the United States, it is still proceeding apace, according to a study released by the National Science Foundation (NSF). Between 1966 and 1975, some 10,000 scientists and engineers emigrated to the United States, the study indicates, though the average annual influx dropped from 11,500 to 6,500 during that period. The two chief influences were an immigration regulation adopted in 1965 which eliminated the preference previously given to European applicants for immigration, and a regulation adopted in 1971 which removed scientists and engineers from the priority list because of high unemployment among scientific workers in the United States.

The result has been an overall drop in the number of scientists and engineers entering the United States, coupled with a marked shift in the relative numbers coming from Europe and Asia.

In 1965, the ratio of scientific emigrants from Europe and Asia was 40% and 28% respectively; by 1975, it had swung to 19% and 56%. Throughout the decade, the ratio of engineers to scientists remained fairly constant at about 2 to 1.

Waste report

The UK National Radiological Protection Board (NRPB) has followed up its recent publication dealing with disposal of high-level radioactive waste on the sea-bed with the release this week of a report studying the ways low-level waste is dispersed in the ocean (NRPB-R58, HMSO, 50p). Disposal of such waste, which consists of contaminated equipment, clothing and rubbish packaged with concrete or bitumen in metal drums that eventually corrode, has gone ahead under international arrangements for some years. The report describes a two-part (short term and long term) mathematical model for estimating maximum con-

centrations of radioactivity in water for continuous disposal, and can be used to assess the ocean's limiting capacity to accept radioactive waste.

Geos switch-on

Switch-on of experiments on Geos started on 29 April. Five out of the seven experiments have so far been tried and are working; the boom deployment programme is progressing satisfactorily. Eight hours of effective data transmission per day will be possible but only about four hours will be beyond 5 earth radii where the experiments are designed to operate. At a longitude of 35° E next week Geos could interact with Northern Scandinavian ground stations, but very little useful data are expected because of the movement of the satellite. Only a few per cent of the original data-taking capabilities of the mission can be realised, putting the IMS in jeopardy. A prompt launch of the spare Geos remains desirable.

EARLY in April the Federation of American Societies for Experimental Biology met once again in Chicago. It was, as always, the windy city, with snow flurries blowing off Lake Michigan. I stayed in the Conrad Hilton Hotel, as I had in 1941, when it was the Hotel Stevens. Some years later, I think in 1956, I had squeezed my way into a doorway of a packed room to hear a paper by Volkin and Astrachan on 'DNA-like RNA'. It was one of the first premonitions of messenger RNA. Prior to this, ribosomal RNA seemed the only possible template for protein synthesis, and its uniformity of composition in different organisms was not compatible with the diversity of their proteins. This year a capacity crowd of thousands sat comfortably in a big new theatre to hear a virtuoso performance by Fred Sanger as he described the nucleotide sequence of Φ X174 containing instructions for 1,849 codons in genes for eight proteins. One of the audience told me afterwards that it was always a humbling experience to listen to a lecture by Fred.

My thoughts turned to Federation Meetings, years ago, when a livelier iris changed upon the burnished dove and sprightly young women scientists caught my bachelor eye, or I tried to catch theirs. Alas, in 1977, I found myself looking automatically at all people with grey hair because I expected to recognise them as my contemporaries; souls that have toiled, and wrought, and thought with me. Such are the dividends of advancing

years. But there are really few experiences so rewarding as that of greeting an old colleague and friend whom one has not seen for a long time.

Federation meetings

THOMAS H. JUKES

I was the final speaker in an evening session in a meeting room at the Conrad Hilton Hotel. A modern note of social disintegration was sounded by an incident that took place within five minutes after I finished; someone stole the slide projector. I never found out if the purloiner was a disgruntled scientist who sought belated revenge because his slides at some meeting had been shown upside down.

The 'poster sessions' in the

McCormick Place Exhibit Hall were obviously very successful. This format has increasingly replaced the old system of 12-minute papers read in an often crowded and usually darkened room. On Tuesday afternoon, for example, there were 13 'regular' sessions in biochemistry and 9 poster sessions. The authors are on hand at their assigned posts, complete with posters, graphs and abstracts, to discuss their work with all passers-by who are interested. This gives much more opportunity for an exchange of views than is afforded by two or three minutes allowed for questions after a regular paper. The Exhibit Hall was, as ever, the scene of a dazzling profusion of intricate biochemical equipment and apparatus. One would not have suspected any slow-down in research.

There was the usual profusion of diverse social gatherings and cocktail hours, ranging from the Annual Meeting and Wine Mixer Association for Women in Science to the Korean Biologists Tea and the Physiology of Exercise Mixer.

I am afraid I have very little sympathy with those who oppose the granting of travel funds for scientists to attend such meetings. At such gatherings, names become changed into people, ideas are exchanged and stimulated, and long friendships are started. The public has garnered sufficient dividends from the progress of the biological sciences in the past 50 years to support the continuation of the Federation Meetings.

news and views

New accelerators for high energy physics

from W. J. Willis

The super proton synchrotron (SPS) at CERN in Geneva is due to be inaugurated officially on 7 May. In this and the following two articles practicing scientists look at future prospects.

A NEW stir of activity among physicists studying elementary particles has become unmistakable. In part due to the excitement generated by the suggestive discoveries of the past 3 years, it has also to do with the sense that visions of important future facilities may become real. In January the SPS, a 400 GeV proton accelerator was commissioned for physics at the CERN site near Geneva, bringing to completion the generation of facilities planned in the 1960s. While these are exploited, discussion of possible future steps grows more serious.

Extension of existing facilities

Some important and interesting developments of the existing facilities are already underway, speeded by competition, the excitement of the new discoveries, their relatively moderate cost, and the fact that complicated institutional arrangements were not required. Two similar storage rings to study the collisions of beams of electrons and positrons at energies up to more than 20 GeV are under construction at the DESY Laboratory, near Hamburg, and at SLAC, in Stanford. The German machine, PETRA, is expected to be completed in 1979 with the Californians' PEP some months behind. The recent experiments on e^+e^- annihilation in the few GeV region led to the rapid discovery of many new particle states and showed that this is a clean and powerful way to study the creation of states containing many strongly interacting particles. The notion that a good many of the discoveries will be made quickly, and the similar schedules for the two machines, have combined to give their construction somewhat the character of a race.

Another ongoing project is the Energy Saver-Doubler at Fermilab, a characteristically bold endeavour which represents the first commitment to build

and operate a large number of superconducting magnets. These will be placed in the existing tunnel and the protons transferred to the new ring at an energy of several hundred GeV. The risk is moderated by the consideration that the project will be justified, as an Energy Saver, even if the magnetic field initially attains only the 2.2 Tesla now provided by the conventional magnets. Of course it is expected that the superconducting magnets will reach fields greater than 4 Tesla, allowing the new ring to accelerate protons to 1 TeV (1,000 GeV). The necessary strengthening of the experimental beams and shielding would then allow a new experimental programme at higher energies and perhaps intensities. The schedule and cost are not firm, but the experimental programme at 1 TeV is certainly several years distant.

These developments open the way to many new kinds of experiment, but it should be pointed out that they do not provide higher centre of mass energies than those already available from the collisions of the two 31-GeV proton beams of the CERN ISR. This falls short of the region of 100 GeV of available energy, where the weak and electromagnetic interactions may reach the same strength. The recent discovery of neutral weak currents supplies a missing link in the argument that these two interactions are different aspects of a single fundamental phenomenon. It is widely believed that when the necessary energy is reached, their unity will become apparent, probably by the creation of a new family of very massive particles which are the quanta of the weak electromagnetic field. In testimony before a Congressional committee several years ago, T. D. Lee drew an analogy between the consequences of this hoped-for unification and the unification of electrical and magnetic forces achieved by Faraday and Maxwell. In this context the PEP-PETRA race can be viewed as an exciting skirmish on the way to the goal sought for so many years.

Colliding beams and electron cooling

Attempts to reach this goal are foreseen on two levels. Both Fermilab and

CERN hope to reach centre of mass energies well above 100 GeV by colliding beam experiments based in large part on the use of existing equipment. At Fermilab, one possibility considered is to store protons in the Energy Doubler at energies up to 1 TeV, and collide them with protons in the existing Main Ring at about 200 GeV, giving centre of mass energies up to 900 GeV. Also, both laboratories are planning to continue the investigation of the technique of "electron cooling" invented and successfully demonstrated by G. Budker in the Soviet Union, to allow the storage of large currents of antiprotons. In this technique, an electron beam is passed through a beam of antiprotons created by the accelerator and captured in a small storage ring. The antiprotons are created with a spread in energy and angle which causes them to fill the aperture of the storage ring. The electron and antiproton beams, which have the same e velocity, are coupled by the Coulomb force. The antiproton beam exchanges its disordered motions with the constantly renewed electron beam, and is damped into a narrow beam occupying only a small part of the storage ring aperture. More antiprotons are injected and the process repeated over many hours, until a large current of antiprotons is built up. These are then injected into the large ring, together with a counter-rotating proton beam, and accelerated to the maximum energy. Apart from a possible advantage of antiproton-proton collisions in creating new states, the noteworthy feature of this scheme is that it requires but a single large ring, and thus allows the conversion of an existing accelerator into a colliding beams facility. This has long been the aim of Budker's group at Novosibirsk, viewed with a certain scepticism by the orthodox accelerator scientists until the recent success. A very different cooling method has also been demonstrated recently at CERN.

In the forthcoming tests, CERN has the advantage of using an existing small storage ring, but the ring Fermilab will construct for tests with protons can also be used for antiproton

accumulation in the final scheme. If all goes well, these efforts could lead to colliding beam experiments in the early 1980s. If this technique is applied to the Energy Doubler, we might see collisions with 2 TeV in the centre of mass in 5 years or so.

Plans for future facilities

These heady visions must be balanced by some cautions. Major extrapolations are involved in these designs, and the event rates which will actually be achieved are most uncertain. The experiments in the region where the weak and electromagnetic interactions become equal are not easy, and involve quite small cross sections. It may be that these projects reach success without being able to perform these difficult experiments in a conclusive manner. In any case, these are attempts to carry off a coup, and will not yield facilities where many experiments can be carried out simultaneously. The more conventional plans to reach the energy goal may prove to be the more important for physics. The discussion of major new facilities proceeds primarily within the traditional framework of the USA, the European collaboration, and the Soviet Union, but efforts to establish a world-wide collaboration have begun to have effects, mainly indirect. The "world accelerator" discussion has been carried out off and on since 1960, but achieved its most interesting stage last May in a meeting at Serpukov. The participants agreed on two points. They undertook

to avoid a needless duplication of facilities. Whether this is an admission of guilt in the PEP-PETRA case is moot, but it has real implications for the next step. It was further agreed that an attempt would be made to fix upon a world facility in about 10 years' time, leaving enough time for one more round of "regional" facilities. The International Union of Pure and Applied Physics was assigned the task of studying some organisation for further work, with US, European, Soviet, and Japanese participation. (A rapid cycling proton accelerator of 10 GeV is now working in Japan.)

The reality of the world accelerator may be uncertain, but the fixing of a kind of deadline for any large regional effort has immediate consequences. As it happens, the US has a mature proposal ready for a decision. This is ISABELLE, a superconducting proton storage accelerator of 200–300 GeV, to be built at Brookhaven, and given a good chance of gaining approval soon. Partial approval has apparently been granted at Serpukov for an accelerator of 2 TeV, called UNK, to be converted to storage rings later. In Europe, it has not been possible to carry out detailed planning for a new facility while constructing the SPS, an expensive instrument whose approval and financing has already created tensions among the CERN collaboration. This is an awkward time to seek bilateral arrangements with the US, since Brookhaven is confident of obtaining approval without further complications.

This situation, and the 10 year deadline, has led to a sense of urgency among European particle physicists. Luck seems to be with them, since the great success of the electron-positron colliding beams has revealed a big gap in the world plans, in that there has been no plan for an e^+e^- machine to reach the goal of 100 GeV or greater, though it is probably possible to build such a machine at a reasonable cost. If the neutral weak currents arise from a heavy particle with a mass of about 80 GeV, this machine would be a superb tool for investigating many new phenomena, and it is in any case a powerful complement to the proton collisions. This idea is now under study by the European Committee on Future Accelerators, and by CERN, along with the LSR, a 400 GeV proton storage ring, and other possibilities.

Ideas for the world accelerator itself are not at all definite. Most often mentioned is the VBA, a proton accelerator (storage ring?) of more than 10 TeV. Part of the enthusiasm for such a project reflects the feeling that one of the major successes of CERN has been to demonstrate that many nations can work together to achieve a common goal, even one involving deeply integrated efforts in complex technology. It would indeed be a happy result if the same success could be achieved on a world wide scale, while providing the next generation of young physicists with completely untrodden territory to explore. □

New physics and new accelerators in Europe

rom B. H. Wiik

OVER the past few years great progress has been made in our understanding of the fundamental laws of nature as revealed by high energy physics. On the one hand, there has been an explosion of experimental discoveries—neutral weak interactions, probably charmed particles, perhaps a new lepton. Obtained at the present generation of high energy accelerators—CERN, DESY, FNAL and SLAC—most of these discoveries support the idea that weak and electromagnetic interactions can be unified in a single gauge theory. These experimental discoveries have been rivalled by a similar theoretical explosion. It now seems possible to suggest that the strong nuclear forces may also be reflections of an underlying gauge theory of quarks. It is even permissible to dream of the super-unification of all elementary particle forces.

Experiment and theory in high energy physics must engage in a continuous dialogue for this progress to continue. Do new quarks exist beyond charm? Are there yet heavier leptons? What is the structure of the weak and the strong interaction? Is there a symmetry between quarks and leptons? Answers to some of these crucial questions may be forthcoming from experimental facilities which are now available or under construction. In Europe the hopes are centred on the ISR and the SPS at CERN and at DORIS and PETRA at DESY.

ISR

At the ISR—the large proton-colliding beams at CERN—a new generation of experiments specifically designed to search for new particles is under way and results are expected within a year. With impressive ease CERN recently commissioned

the SPS, a new 400 GeV proton synchrotron. The SPS supports, among other studies, extensive programmes in neutrino physics and high energy muon scattering. These lepton beams are well suited for the production of hadrons composed of new quarks and the experiments are also expected to give important clues to the nature of the strong interaction.

PETRA

The commissioning of PETRA, the high-energy e^+e^- accelerator now under construction at DESY, is little more than a year away. This storage ring will initially explore the energy range up to 30 GeV in centre-of-mass and ultimately probe even beyond 50 GeV. As has been proven with SPEAR at SLAC and DORIS at DESY, e^+e^- collisions are powerful sources of new particles, both quarks and leptons. At the highest PETRA energies the neutral

weak interaction may start to become comparable to purely electromagnetic effects.

Need for higher energies

However, there are crucial questions which can only be settled at energies well above those available with the present accelerators. From energies of a few keV to a few hundred GeV the weak interaction is well described by the point Fermi interaction resulting in a total cross section increasing linearly with energy. For the weak interaction to be consistent with unitarity, one generally assumes that it is mediated by the exchange of heavy vector bosons, to which gauge theories usually give masses between 50 GeV and 100 GeV. The simplest gauge model which relates the electromagnetic and the weak interaction predicts a charged $W^\pm$ boson with a mass around 65 GeV and a neutral Z^0 boson with a mass about 80 GeV. It is obviously crucial to find the intermediate vector bosons and to directly demonstrate that the electromagnetic and the weak interactions are simply manifestations of a single interaction. Another very important question which requires super-high energies to answer, is related to the strong interaction. If strong interactions are described by an asymptotically free gauge theory of quarks, then they should grow progressively weaker at very short distances. Short distances can only be probed at very high energies.

There have been several recent studies in Europe and elsewhere of accelerators with sufficiently high energies to confront these questions in the near future. At present, plans in Europe are centred on upgrading existing facilities at CERN. The boundary conditions are low cost and a reasonably short time-scale. Two projects which meet both these conditions take advantage of the excellent properties of the SPS to collide either antiprotons or electrons with the protons in the main ring.

Upgrading SPS

In the $p\bar{p}$ option protons and antiprotons are injected into the SPS in opposite directions and made to collide in one or perhaps two of the long straight sections. The SPS can run continuously at 270 GeV resulting in a cms energy of 540 GeV for the $p\bar{p}$ system. This option will provide a first glance at strong interactions in a new energy region where cosmic ray studies give tantalising indications of novel phenomena. It also offers the enticing possibility of directly producing the $W^\pm$ and Z^0 . Rates for these processes have been estimated using a Drell-Yan mechanism and found to be acceptable provided a luminosity of at least $10^{30} \text{ cm}^{-2} \text{ s}^{-1}$ can be reached. Recent results from the ISR on stochastic cooling and from Novosibirsk on electron

cooling—both used to increase the phase space density of the antiprotons—may make such luminosities within reach. A working group at CERN is now studying the following scheme which combines both methods. Protons from the 28 GeV proton synchrotron are used to produce antiprotons with momenta around 4 GeV/c. These are injected into a small storage ring, cooled stochastically, decelerated to 100 MeV kinetic energy and transferred to a second ring where they are further cooled by an intense electron beam travelling with the same velocity as the antiprotons. To accumulate a sufficient number of antiprotons this process is repeated many times over—in fact it takes nearly a day to accumulate the 10^{12} antiprotons needed. After accumulation, the antiprotons are transferred to the SPS and accelerated together with the protons to high energies. This is a very exciting project and a vigorous study is now under way to see if it can be realised with luminosities of $10^{30} \text{ cm}^{-2} \text{ s}^{-1}$ or above. A similar project is also under study at FNAL.

In the electron-proton option the proponents suggest injecting electrons from a small synchrotron like NINA into a large electron ring mounted in the SPS tunnel. Electrons with a maximum energy of 25 GeV to 30 GeV are made to collide with protons of energies from 140 GeV to 400 GeV during a normal or somewhat extended SPS cycle, with an intermediate flat top. Collisions can take place in two interaction regions and the peak luminosity may be of the order of $10^{32} \text{ cm}^{-2} \text{ s}^{-1}$. This scheme allows the normal SPS programme to continue and since the protons only remain for very short times in the SPS ring, all problems connected with storing a tightly bunched proton beam are minimised.

The proposed electron-proton option will extend the momentum transfer and energy range presently available with the neutrino and the muon beams at the SPS or at FNAL by nearly two orders of magnitude, probing a region where a point-like weak interaction would be stronger than the electromagnetic interaction. However, according to gauge theories the weak interaction will be damped such that both interactions will be of similar strength. The experiments will elucidate in detail how the weak and the electromagnetic interactions are unified—do only one $W^\pm$ and one Z^0 exist as presently conjectured, or is a more complicated mechanism involving many new heavy bosons responsible? Crucial information on the strong interaction can also be obtained by using virtual photons to probe the strong forces at short distances. Do they indeed weaken as the relevant distances shrink? Conclusive tests of this conjecture require momentum transfers well above those available at present accelerators.

Both the $p\bar{p}$ and the $e\bar{p}$ option will

greatly advance our understanding of nature and they are both natural upgradings of the present SPS accelerator. Detailed studies of technical feasibility, and estimates of the cost and the interference with the SPS both during construction and operation are now under way for both projects, with the aim of making a full evaluation of both options by the end of 1977.

Future accelerators

Apart from exploiting existing facilities, one might also be optimistic and hope that Europe will be able to construct a large new accelerator within the next 10 years.

What questions might then be pressing, and what sort of large new accelerator would be needed to answer them? Probably we will want to study in detail the decays and interactions of the intermediate vector bosons. Do they have the characteristic gauge couplings apparently necessary for a calculable renormalisable theory? Does the debris of $W^\pm$ and Z^0 boson decays contain as yet unknown quarks or leptons? But by that time we may hope to be probing beyond gauge theories. In all such models yet constructed, the mass differences between hadrons and leptons, and between the photon and the vector bosons, arise by breaking the gauge symmetry with the Higgs mechanism. The associated point-like scalar Higgs particles are probably very difficult to find, but may be our only window into a world beyond the gauge principle. Perhaps also the super-unification of the strong with the weak and electromagnetic interactions will be another crucial issue 10 to 15 years from now.

Many members of the European high energy community feel that these questions can best be answered by colliding electrons and positrons at very high energies. The results of first studies of such large e^+e^- rings were reviewed at a week-long working meeting organised by ECFA (European Committee for Future Accelerators) at DESY at the end of February this year (see accompanying article). This meeting created much enthusiasm among the participants and detailed feasibility studies of such an accelerator are now under way. Besides the arguments of pure physics, there are also strong political arguments for an e^+e^- ring as the next major European high energy project. These arguments are based on the fact that large proton synchrotrons and proton-proton colliding rings in the multi-TeV range are now under active consideration in both the US and the USSR. A European high energy e^+e^- ring would therefore be unique and fit well into attempts to coordinate the construction of new high energy accelerators on a world-wide basis. □

The accelerator after next

from D. J. Miller

"WHY have a conference about the accelerator after next, when we are just building the next one?" That is the question a lot of us were asking as we flew to Hamburg on 22 February for a 6-day working meeting on electron-positron storage rings of 100 GeV (the LEP, Large Electron Positron project). The organisers, ECFA—the European Committee for Future Accelerators—seemed to be looking a very long way into the future but a number of the participants argued that we should commit ourselves to building such a machine as soon as the money can be found.

The reason for their urgency lies in the present theoretical situation. Results from the present e^+e^- storage rings, from CERN and from Fermilab are giving increasingly firm and consistent support to the idea of charm and its relation to the neutral current in weak interactions. As a consequence, theorists are building more and more detailed models of elementary particles, and predicting quite specific properties for the forces which govern their interactions. The final unification of the weak, electromagnetic and strong forces has not been written down yet, but many parts of the unification scheme exist and will probably survive in something like their present form. In particular, a family of massive particles, the intermediate vector bosons ($W^\pm$ and Z^0), is required to account for the weakness of the weak interaction, and another family of 'Higgs bosons' is needed to relate the $W^\pm$ and Z^0 to the photon the carrier of the electromagnetic force. Precise predictions exist for the masses of the $W^\pm$ and Z^0 , though nobody claims that these predictions are unique. It is also expected that, as e^+e^- collision energies are increased, the weak interaction should grow in strength compared with the electromagnetic force. At the predicted mass of the Z^0 , 80 GeV/ c^2 —equivalent to 40 GeV on 40 GeV e^+e^- collisions—one of three things should happen. There could be a resonance, similar in some ways to the ψ and ψ' but even more interesting to analyse because its decays would tell us exactly how the weak neutral current interaction couples to every other kind of particle. There could be a steady increase of the weak interaction rate which would completely swamp the falling electromagnetic rate. Or there might be

a slow levelling-off of the increase in the weak interaction rate, with no resonance. Such a result would set a lot of puzzles, but their answer would come directly from a study of the events seen.

If the Z^0 resonance is seen, then it is expected that pair production of W^+ and W^- would also occur at a slightly higher energy, and at these energies it might also be possible to observe the production of Higgs bosons by way of $W^\pm$ or Z^0 intermediate states.

Some theorists are sufficiently confident in these predictions that they say we should go ahead as fast as possible and build the LEP machine. Others are more cautious. The first two 15 GeV on 15 GeV e^+e^- machines will not work until 1978 (PETRA in Hamburg) or 1979 (PEP in Stanford, California). The CERN SPS is just taking its first data. A large number of the predicted effects will begin to be seen at the 5 to 10% level with these devices. Perhaps we can get some more indirect evidence about the masses of the $W^\pm$ and Z^0 from neutrino interactions. Then there are relatively cheap advances which could be made by adding an antiproton-proton facility (270 GeV on 270 GeV) to the SPS, or by adding a 25 GeV electron ring to collide with 270 GeV SPS protons. Above all, money is tight and may be getting tighter. Who would pay for a new machine costing over one thousand million Swiss francs to build, and consuming over one hundred megawatts of power?

Electron machines are very greedy for power because the beams radiate energy away in the form of synchrotron radiation. That is why it is much easier to build high energy proton accelerators than electron accelerators. But electron-positron collisions seem to be a much better way of doing high energy physics. When protons collide at high energy the really interesting part of the interaction is between the constituent parts of each proton, the three quarks. This means that, on average, only one third of the energy of each beam is actually available in the basic quark-quark collision, compared with e^+e^- collisions where all the energy of each beam is concentrated in one particle. In addition, in proton-proton interactions, the quark-quark collision is accompanied by a splash of relatively uninteresting particles from the other two 'spectator' quarks in each

proton. The most important class of electron-positron collisions is much simpler to understand because the initial particles are completely annihilated, and the final state is produced in a well-defined way.

The ECFA working-meeting reviewed the theoretical and technical case for building an LEP machine. Possible detectors were discussed and it was clear that the cost of detectors for colliding-beam machines goes up with energy in a much gentler way than the cost of detectors for fixed-target machines such as the SPS. Perhaps the most vital discussions were on the feasibility and costs of the e^+e^- machine itself. Burt Richter from Stanford had made a preliminary investigation of the parameters of a 100 GeV on 100 GeV storage ring. He based his cost estimates on the PEP ring, but suggested that a much bigger machine might gain a considerable benefit from mass-production of components. Other accelerator designers checked his calculations and confirmed that the machine was certainly feasible, even without great advances in technology. One very desirable technical innovation was pointed out. Large numbers of radio-frequency cavity resonators are needed all round the machine to provide the accelerating field which replaces beam energy lost in synchrotron radiation. But half the energy supplied to these cavities does not go into the beam; it is dissipated by resistive losses in the cavity walls. If reliable superconducting cavities can be developed these losses could be almost eliminated. Small laboratory models have been built, but a major programme of research will be needed before production models of superconducting cavities can be designed.

The final opinion of the meeting was very positive. This is the next major accelerator project that should be proposed. It is probably not too big for Europe to build on her own, although collaboration from the USA or elsewhere might be desirable. It would give direct answers to the most important theoretical questions, whereas all other machines, existing or planned, will only give indirect answers. What must now be decided is how to match an LEP project to existing commitments and how to convince governments that the expenses will be worthwhile. □

THE presence of envelope glycoproteins of oncoviruses (the new name for oncornaviruses (Fenner *Virology* **71**, 371; 1976)) on the surface of normal cells has been known since the recognition of murine G_{IX} antigen and of chick helper factor in 1969. Since then there has been much discussion of whether the expression of endogenous viral antigens has a functional role in cellular differentiation. Certainly there is differential expression of viral antigens in different tissues and at different stages of development, but Strand, August and Jaenisch in the February issue of *Virology* (**76**, 886; 1977) conclude from studies of oncovirus gene expression in embryos of different inbred mouse strains that viral antigen synthesis is incidental to differentiation. While I agree that embryos of mice or chickens that show minimal endogenous viral gene expression appear to develop quite well, it is worth noting that feral mice and chickens (jungle fowl) do express viral antigens, so one can say at least that there is no natural selection against viral antigen synthesis. Furthermore, Chen and Vogt in the same issue of *Virology* (**76**, 740; 1977) find that oncovirus envelope glycoproteins are detectable in a variety of avian species.

In this week's *Nature*, (page 23) Elder, Jensen, Bryant and Lerner describe a more detailed study of the glycoproteins (gp 70) related to C-type oncoviruses in mice. By analysis of serotypes and of tryptic peptide maps, they can divide gp70 molecules associated with normal tissues into different groups, more or less related to gp70 specificities of virus isolates. Now most mouse strains inherit several distinct oncovirus genomes

Oncoviruses and cell membrane antigens

from Robin Weiss

and this may account for much of the polymorphism. For instance in strain 129 mice, the serum gp70 resembles that of xenotropic virus, whereas seminal fluid gp70 is more closely related to the FMR group of viruses, not previously thought to be endogenous. Some of the tissue gp70-like molecules may not be linked to oncovirus glycoproteins at all. We do not know whether oncovirus glycoproteins have evolved from cellular antigens or *vice versa*, although it is well known that oncoviruses readily recombine for this genetic marker.

If viral glycoproteins serve as differentiation markers on the surface of normal cells, one might also expect cellular membrane proteins to be assembled into virus envelopes. In fact, this has been evident since de Thé, Becker and Beard (*J. natn. Cancer Inst.* **32**, 201; 1964) demonstrated the presence of leukocyte membrane ATPase in the envelope of avian myeloblastosis virus. Indeed, Beard used this enzyme activity as a biochemical assay of virus particles. Aupoix, Huppert and Vigier (*C. r. hebdom. Acad. Sci. Paris* **282**, 1379; 1976) have demonstrated chick cellular antigens in Rous sarcoma virus particles which are inactivated by treatment with anti-chick serum plus complement, and Hecht and Summers (*J. Virol.* **19**, 833; 1976) have shown that vesicular stomatitis virus picks up H-2 antigens when grown in mouse cells. What is most intriguing, how-

ever, is the report by Bubbers and Lilly last month in *Nature* (**266**, 458; 1977) that Friend virus particles selectively incorporate H-2D^b antigen. It is interesting enough that one particular histocompatibility antigen is selectively assembled in the virus envelope but Bubbers and Lilly further point out that the H-2^b haplotype confers a relative resistance to Friend disease mediated by T-cell cytotoxicity against associative recognition of both viral and H-2^b antigens on the cell surface (Blank, Freedman & Lilly *Nature* **260**, 250; 1976). Thus the association of membrane antigens which act in Zinkernagel and Doherty's (*J. exp. Med.* **141**, 1427; 1975) 'altered-self' recognition system on the cell surface may also be reflected in the virus envelope. Lindenmann (*Biochim. biophys. Acta* **355**, 49; 1974) has argued for many years that viruses could be exploited as immunological adjuvants; complexes of viral and cellular glycoproteins in virus envelopes might be most potent immunogens.

The degree of selectivity of the assembly of H-2^b into Friend virus is a little surprising in view of the variety of unrelated glycoproteins that enveloped viruses can assemble. Perhaps this is most strikingly seen in phenotypic mixing between unrelated viruses, where the 'foreign' antigen can be detected by changes in the infectivity of the virus (Zavada *Methods in Biology*, **6**, 109; 1977). This is how Chen and Vogt (*op. cit.*) detected functional viral glycoproteins in various species of pheasant and quail. No less than seven other papers in the same issue of *Virology* report studies on the assembly and behaviour of glycoproteins in enveloped animal viruses.

Cathodoluminescence topography

from John Walker

DIAMONDS are reputed to look good in candlelight; to the scientist they look even better in electron light (cathodoluminescence—the emission of light during bombardment by electrons, as in a TV screen). Cathodoluminescence topography is a technique which has developed relatively recently and complements the older techniques of X-ray and UV topography. Scientists at the University of Bristol have recently published (Hanley, Kiflawi & Lang *Phil. Trans. R. Soc.* **284**, 329–368; 1977) their fascinating results on topo-

graphically - identifiable sources of cathodoluminescence in natural diamonds, including some fine colour photographs.

Their photographs carry a message, which as yet cannot be entirely deciphered. For example, a greenish-yellow luminescence system denoted H3, which is well-known from previous non-topographic studies, is observed at slip traces and dislocations and at 'platelets' (planar precipitates on {100} planes—see *Nature* **266**, 209; 1977). However, the usual method

of producing the H3 defect is to irradiate the diamond with electrons or neutrons and then anneal it. Now, Hanley *et al.*'s diamonds might have been irradiated by natural radioactivity—indeed some of them undoubtedly had been, as discussed below—but such damage is confined to a thin surface layer. Hence these H3 defects, lying deep within the crystal, must have been produced by other means.

It is known that the H3 defect is composed of a radiation damage product (probably a vacancy), trapped at

the 'A' form of nitrogen aggregate (probably a $\langle 111 \rangle$ -oriented substitutional nitrogen 'molecule'—see *Nature* **265**, 317; 1976). One can speculate that it could also be created without irradiation by slip in the same way as some EPR centres apparently are. In this process two adjacent $\{111\}$ planes of the crystal move relative to each others, and any unfortunate nitrogen molecules bridging the planes are sheared apart (Scherbakova *et al.* *Sov. Phys. Dokl.* **20**, 725; 1975).

Another puzzle is that H3 is not normally observed in type II diamond, whereas Hanley *et al.* detect the slip traces and the H3 luminescence in type II as well as type I regions in their specimens. One way in which these problems might be resolved is to deform plastically diamonds in the laboratory, and study their cathodoluminescence before and after.

Polarised H3 luminescence was observed from the platelets. Platelets were originally thought to be composed of nitrogen. Recent evidence suggests that they may be carbon in some interstitial arrangement, though there is still controversy on the matter, as Hanley *et al.* emphasise. On the carbon interstitial hypothesis one would have to assume that the H3 defects merely decorate the platelets rather than being an integral structural part of them, though in that case it is a little surprising that the luminescence is polarised. The uniformity of the luminescence along a platelet strongly suggests that they are an intrinsic part of the structure, and hence that the platelets do contain nitrogen. It is worth recalling that Lang's model for the platelets (*Proc. Phys. Soc.* **84**, 871; 1964) contain sets of $\langle 100 \rangle$ -oriented nitrogen 'molecules'; this similarity with the A centres may explain the H3-luminescing platelets.

Hanley *et al.* also observed infrared emission from the platelets. Kiflawi and Lang (this issue of *Nature*, page 36) have confirmed this observation and have shown that it is highly polarised, and due to a broad-band system peaking at 1.25 eV, previously known to be connected with the platelets. This also seems to be an intrinsic platelet property rather than decoration by something else.

Other luminescent systems known to involve radiation damage were detected by Hanley *et al.* They included the H4, 3H (*sic*) and 575 nm systems, and were usually present in a thin surface layer whose thickness (30 μm) corresponded very well with the expected penetration depth of α particles. Hence they were probably created by natural radioactivity.

Hanley *et al.* draw attention to the intimate relationship between optical properties and growth features, and to

the inhomogeneity of most diamonds. They strongly recommend detailed examination of specimens, preferably by X-ray topography, before any experiments in which homogeneity matters. This has proved a pitfall in the past, particularly where correlation of different properties has been involved.

Since their measurements were done at or above room temperature, and largely in the visible spectral range 1.8 to 3.2 eV, extensions of the work are awaited with interest. Lower temperatures should bring greater sensitivity in the detection and identification of luminescence, and a wider spectral range might lead to further associations between point defects and growth features or other extended defects.

Diamond is the ideal subject for cathodoluminescence topography. It is transparent and shows a great many luminescence systems in the visible and near-visible spectrum. Furthermore, the processes by which it is synthesised, both industrial and natural, are not well understood; topographic studies give us some idea of how diamonds grew and what subsequently happened to them. Whether the technique can be applied as profitably to other materials is an open question. $\square$

How aseismic ridges behave

from Peter J. Smith

As newly produced oceanic lithosphere moves away from a spreading centre it cools and contracts. The result is that the average depth to the seafloor, which is $2,500 \pm 300$ m at active oceanic ridges, gradually increases with age until it is $5,800 \pm 300$ m for lithosphere formed during the late Jurassic-early Cretaceous. But although this general relationship between depth and age applies to most oceanic lithosphere, all the oceans contain many anomalously shallow features such as plateaus, rises and aseismic ridges. Such bodies have been relatively neglected by geologists, presumably because they appear not to form part of first-order seafloor spreading theory. Yet some information is available on aseismic ridges, not least from the Deep Sea Drilling Project (DSDP) which has now sampled at least 13 of them.

In an attempt to discover whether anything can be said about the origin and subsequent behaviour of such ridges, Detrick *et al.* (*Earth planet. Sci. Lett.* **34**, 185; 1977) have now brought

all the DSDP results together. And apparently something can be said. Consider, for example, the group of major aseismic ridges comprising Ninetyeast Ridge, Chagos-Laccadive Ridge, the southeast Mascarene Plateau (all Indian Ocean), Walvis Ridge and Rio Grande Rise (south Atlantic). DSDP cores indicate that all five contain older shallow-water sediments or subaerial material (ash, for example) and that the younger sediments become progressively more deep-water and more characteristic of deposition in an open marine environment. It would seem from the sedimentary record, therefore, that these ridges formed at or near sea level and have subsequently subsided by up to several thousand metres.

But by what mechanism did they subside? To find out (or perhaps to test a preformed hypothesis?) Detrick and his colleagues have determined, for each core which penetrated the volcanic basement, the age of the basement (usually from the palaeontological age of the basal sediments) and its depth corrected for the isostatic loading of the overlying sediments. When these ages and depths are plotted together, most of the points are found to lie in a curved band which bears a remarkable resemblance to the curve of age against the depth to be expected on the assumption that ridges subside at the same rate as normal oceanic crust. The agreement is not exact, for in addition to the scatter of points there is a tendency for the measured subsidence to be a few hundred metres less than that predicted. Nevertheless, it is clear that all five ridges have subsided at a rate comparable to that of normal oceanic crust.

That being the case, Detrick *et al.* propose a simple model in which an aseismic ridge forms at a spreading centre by excessive volcanism which builds the ridges up to sea level. By analogy with large-scale shield volcanism, the construction of the ridge is taken to be fairly rapid (perhaps 0.5–1.5 Myr) and the isostatic adjustment of the crust to the new ridge is assumed to occur almost simultaneously with the volcanism. Then all that happens is that the spreading, subsiding lithosphere carries the ridge along and down with it. In other words, the subsidence of an aseismic ridge is a purely thermal effect associated with the cooling and contraction of the lithosphere upon which the ridge is built.

Of course, real ridges do not often conform exactly with the model. At formation they may lie slightly above or below sea level; and since their tops are seldom if ever perfectly horizontal planes, there will be variations in level even within a single ridge. Moreover, a ridge may form slightly off the spreading axis, giving it an age rather younger

than that of the surrounding crust; and even a small deviation from the axis can produce a significant effect here because the depth-age curve close to a spreading centre is steep. Then for a ridge formed subaerially, the amount of subsidence occurring before the ridge top sank below sea level will not be recorded in the measured subsidence. The net result of all such effects will be to produce a scatter of points along the depth-age curve and also to bias the points towards too small a measured subsidence.

In the circumstances, then, it is perhaps surprising that the difference between the measured subsidence and the subsidence predicted from the behaviour of normal crust is generally no more than 300–400 m. However, such relatively small deviations apply only to the five ridges under consideration; other aseismic ridges conform much less well. For example, the Iceland–Faroe Ridge evidently formed above sea level and remained that way for at least 15 Myr before beginning its subsidence. On the other hand, Coiba Ridge, Carnegie Ridge and Cocos Ridge (Pacific) seem to have formed well below sea level and are thus now unusually deep. Then again, Madagascar Ridge, Broken Ridge and the Naturaliste Plateau (Indian Ocean) seem to have complicated histories of subsidence and uplift.

In view of these exceptions, it seems that the Detrick model can make no claim to widespread application. Yet there is more to it than that. It could be said, at least as an hypothesis, that the model applies generally to all aseismic ridges that form at spreading centres and at sea level. It does not necessarily follow from this, however, that all aseismic ridges are formed at spreading centres and at sea level. What may be true nevertheless is that, wherever a ridge forms, when it subsides it does so at a rate comparable to that of normal oceanic crust and as a direct result of the cooling and contraction of the lithosphere. □

New twists in bacterial flagella

from Michael Spencer

SINCE the last comment in these columns (*Nature*, 263, 370; 1976) more light has been shed on a number of problems relating to the structure of bacterial flagella. The first is the geometrical puzzle set by bacteria having more than one flagellum: if all are helices undergoing real or apparent rotation, can they avoid tangling together? It is a simple matter to test

this empirically by twiddling two pieces of wire between the finger and thumb, but a rigorous analysis is more daunting. Macnab (*Proc. natn. Acad. Sci. U.S.A.* 74, 221; 1977) has now tackled the problem using geometrical and hydrodynamic theory, assisted by working models.

His conclusions confirm the finger-and-thumb analysis, showing that if a group of left-handed helices starts to rotate in a counterclockwise sense when viewed looking towards the basal points of attachment, the flagella are constrained to rotate in phase with each other and will continue to do so without hindrance; they do, however, undergo some distortion so as to form a compact bundle. This is what is observed in the normal swimming of bacteria. When the direction of rotation reverses, however, the helices should rapidly interlock so as to prevent further rotation (unless the flagella are very short, as occurs in some species). If both the handedness of the helix and the sense of rotation are reversed, jamming is not expected and normal forward motion can be resumed, with the flagella pointing to the rear.

Now comes the surprising part. Macnab and Ornston (*J. molec. Biol.* 112, 1; 1977) report that a bacterium does not simply stop when the flagella reverse their rotation: the bundle flies apart, and the clockwise-rotating flagella are observed to have the smaller pitch characteristic of the 'curly' mutant. As first shown by Shimada *et al.* (*Nature* 254, 332; 1975), this has a right-handed helix. If the process is slowed down by irradiating with blue light in a high-viscosity medium these flagella sometimes form a curly bundle, giving forward motion again. Normally, however, there is a brief period of 'tumbling' followed by reversion to the previous state: a bundle of left-handed helices is reformed and the organism swims off in a new direction.

This periodic change of direction is an essential part of the chemotactic response, for external stimuli seem to influence the probability of tumbling: movement in a favourable direction suppresses the urge to tumble. This applies whether the bacteria are moving towards an attractant or away from a repellent, and must involve some kind of memory mechanism linked to the receptors (Macnab & Koshland *J. molec. Biol.* 84, 399; 1974). The observed change of helix parameters seems to be essential, for without it the bacteria might simply stop and start again without changing direction, and there would be no point in reversing the sense of rotation. Only in certain special cases can backward motion be

sustained.

The obvious question is "What makes the helix change when rotation is reversed?" After studying a number of mutant forms and the effects of abnormal growth media, Macnab and Ornston conclude that the torsional stress arising from a reversal of rotation actually induces a change in the packing of the flagellar subunits, so that the structure flips from a left-handed to a right-handed helix. On removal of the stress, the structure clicks back into its normal shape. Their paper includes a number of photographs in which the transition is caught propagating out from the base of the flagellum, where torsion is expected to be greatest. As confirmation of this idea, abnormal curly flagella are observed to flip into the normal form under stress—the reverse of the normal process.

An outstanding problem—apart from the key question of how rotation is generated—is the nature of the forces that hold the subunits of a flagellum together. Kamiya and Asakura (*J. molec. Biol.* 108, 513; 1977) have some new evidence which supports the idea that electrostatic charge interactions are important. It has been known for some time that reconstituted flagella from *Salmonella* can change from the left-handed normal helix to the right-handed curly form on reduction of the pH. Kamiya and Asakura now report that the same transition can be induced by an increase of pH above neutrality. In this case, as for the acidic transition, the curly form is attained by passing through an intermediate ('coiled') form. It can hardly be a coincidence that this sequence of transitions is just what would be expected from a geometrical packing model of the kind suggested by Calladine (*J. theor. Biol.* 57, 469; 1976). It looks as if the ionisation induced by extremes of pH causes longitudinal rows of subunits to rearrange themselves, causing a discrete change in the helix parameters for each row thus transformed. Calladine's working hypothesis of a 'hinge' between subunits, giving two alternative arrangements, is supported by several biological examples; the latest to be described is tomato bushy stunt virus (Winkler *et al.* *Nature*, 265, 509; 1977).

This latest work on flagella illustrates how electrostatic and mechanical forces can separately induce a similar structural change. Macnab and Ornston make the point that a stress-induced transition may be relevant in other systems having regularly-arranged subunits. Who knows, at present, whether it might not be at the heart of muscular contraction? But that is another story. □

Wanted alive—but handle with care

PHYSIOLOGY laboratories in Britain, Germany and the United States are urgently seeking suppliers of the tropical giant water bugs of the genus *Lethocerus*, whose flight muscle is one of the most important preparations used in the study of the molecular mechanisms of contraction in insect flight muscle.

During a symposium held recently in Oxford, UK, the problem of obtaining living material from tropical countries and the lack of success in breeding these bugs in the laboratory were discussed. The laboratories shown in the table are all now in the market for the living insects; the table shows approximate requirements and acceptable species. They would be glad to hear from anyone who can provide these insects and would be willing to make contracts with reliable suppliers. Transit costs would be refunded and all prices are quoted in US dollars.

These giant bugs are aquatic but are easily collected when they fly to lights in damp weather—in the rainy season now approaching in many of the countries where they are found. Provided they are individually restrained in envelopes with an adequate air supply, up to 50 can be packed in a perforated tin and sent by air freight. These insects have a poisonous bite and should be handled with care.

The proceedings of the symposium will be published by Elsevier-North Holland Biomedical Press later this year, entitled *Insect Flight Muscle*.

Lethoceros: \$5,000 market

A hundred years ago

M. HENRY GIFFARD is constructing, near the Champ de Mars at Paris, a workshop for the preparation of sulphate of iron. The apparatus was tried for the first time last Friday, when the balloon *Eole* was inflated in an hour and a half, and was sent up with an aeronaut. The capacity of the balloon being 220 cubic metres, the rate of production is very satisfactory. It is expected that the sale of sulphate will cover almost all the expenses, so that numerous scientific ascents may be made in the ensuing summer. The monster captive balloon of 20,000 cubic metres will be inflated by the same process.

Evidence of Precambrian continent–continent collision in Western Norway

Erling J. Krogh

Mineralogisk-Geologisk Museum, Sars'gate 1, Oslo 5, Norway

Norwegian gneiss eclogites are formed in situ within the temperature–pressure range 300–800 °C, 8–22 kbar. The regional $K_{D(FeO/MgO)}^{ga+cpx}$ distribution pattern indicates an increasing P–T trend towards the coastline. Retrograde reactions indicate a nearly isothermal uplift history. A plate tectonic model, involving continent–continent collision and subduction is proposed for the formation of these eclogites.

ECLOGITES commonly occur as bands and lenses within the West Norwegian gneiss region. The surrounding rocks are mica-rich schists, biotite–plagioclase gneisses and biotite–two–feldspar gneisses^{1–4}. They are assumed to be metamorphic equivalents of original supracrustal rocks. The metamorphism of these gneisses lies in the almandine amphibolite facies, but eclogites are also found within a complex of granulite facies rocks².

K–Ar ages on hornblends from the eclogites give 1,750–1,850 and 980–1,170 Myr, and micas give 370–415 Myr (ref. 5). A three point K–Ar isochron based on data from McDougall and Green⁶ (sample no. 756) gives ~940 Myr (W. L. Griffin, personal communication). Rb/Sr whole rock datings on the surrounding gneisses give ~1,700 Myr (refs 4, 6) and ~1,000 Myr (ref. 7), while mineral Rb/Sr (ref. 7) and U/Pb (ref. 8) data indicate a Caledonian effect. These datings suggest that the eclogites are of the same age, and have the same crustal history as the surrounding gneisses.

The formation of Norwegian eclogites has, however, long been a controversial subject. O'Hara and Mercy⁹ suggest that the eclogites were emplaced into the gneisses as wedges of crystalline rocks that were derived from the upper mantle. Lappin¹⁰ believes that the eclogites were brought to near-surface conditions by an upwelling mantle (for example a mid oceanic ridge), and taken along with a moving oceanic lithosphere plate to a subduction zone. As the subducted lithosphere went downwards, the eclogites were mechanically mixed in with the overlying continental material, where we find them today. The main argument for a mantle origin of the eclogites is that the P–T conditions necessary for eclogite formation are not realised within the crust^{9,10}. Lappin¹⁰ further argues that the maximum pressure during the metamorphism of the gneisses did not exceed 10 kb, a "limiting pressure assigned to amphibolite facies by various authorities".

Bryhni² argues from field and structural data that although some of the eclogitic bodies are tectonic inclusions, they have not been transported over long distances relative to the enclosing gneiss. Most of the eclogites, however, form concordant lenses or bands parallel to the foliation of the gneiss. There is structural and petrological evidence for the formation of eclogites *in situ* together with the enclosing gneisses^{3,4,11–14}. Griffin and Råheim¹² describe dolerites that are partly altered through coronites to eclogites, and show that they were formed *in situ* at the same P–T conditions as the eclogites in the same

area. This implies that eclogites may be formed within the crust.

I have recently discovered blueschist facies mineralogy in eclogites from the Sunnfjord area, also indicating a crustal origin of these rocks.

Samples from more than 30 different localities (Fig. 1) were chosen for a detailed study of the Norwegian gneiss eclogites. The general primary mineral assemblage in the eclogites from Sunnfjord area is garnet + omphacite ± phengite ± paragonite + barroisite/glaucophane + quartz + rutile ± kyanite ± zoisite. In the Nordfjord, Sunnmøre and Nordmøre areas, the general primary mineral assemblage is garnet + omphacite + amphibole ± phengite ± quartz + rutile ± kyanite ± zoisite. In these areas orthopyroxene bearing eclogites are also fairly common. The primary mineral assemblage in these rocks is garnet + clinopyroxene + orthopyroxene ± amphibole ± quartz + rutile. Primary plagioclase is not present in any of the examined samples, except from albite inclusions in garnet in

Fig. 1 Locations of analysed ga+cpx pairs from eclogites, with minimum $K_{D(FeO/MgO)}^{ga+cpx}$ values. The iso- K_D -lines show a regular pattern, with K_D decreasing towards the coastline. Some of the given K_D values are mean values from several small bodies within the same area.

some few cases. Secondary plagioclase is, however, observed both together with secondary orthopyroxene as a breakdown product of quartz + garnet, and as symplectitic intergrowths with secondary diopside or hornblende. These secondary features are most common in the NW part of the area.

Experimental work has shown that the distribution of Fe^{2+} and Mg between garnet and a co-existing FeMg-mineral is a function of temperature and pressure¹³. If the distribution coefficient is defined as

$$K_D = \frac{(\text{FeO/MgO})^{\text{ga}}}{(\text{FeO/MgO})^{\text{FeMg-min}}}$$

then the K_D value at constant P will decrease with increasing temperature, and vice versa. Similarly, the Al_2O_3 content of orthopyroxene coexisting with garnet has also shown to be a function of T and P (refs 15–19). At constant P the Al_2O_3 content in orthopyroxene will increase with increasing T .

To calculate pressures and temperatures of formation for the eclogites, EMP analyses of coexisting ferromagnesian minerals were done. Special attention was paid to the chemical zoning of the minerals.

Ferric iron was calculated assuming stoichiometry. This method seems to give very consistent results, and EMP analyses of five samples from one eclogite body in Sunnfjord give a variation in $K_D^{\text{ga+cpx}}(\text{FeO/MgO})$ of 12.6 to 13.4. Assuming an analytical error in SiO_2 of $\pm 1\%$ by weight, this will result in a maximum variation in K_D in one of these samples of 10.9 to 13.8, which corresponds to a temperature difference of only 40 °C.

The methods used for determination of P and T are those worked out by Wood¹⁶ (Al_2O_3 in opx), Råheim and Green¹³ ($K_D^{\text{ga+cpx}}(\text{FeO/MgO})$), and Krogh and Råheim ($K_D^{\text{ga+ph}}(\text{FeO/MgO})$; work in preparation). The presence of either ga+cpx+ph or ga+cpx+opx will thus allow simultaneous solutions of two equations to give unique values of T and P . If both phengite and orthopyroxene are missing, the $K_D^{\text{ga+cpx}}$ (ref. 14) can be combined with experimental and empirical work on the jadeite content of clinopyroxene^{20,21} to give P – T estimates. This will, however, only give minimum values of both P and T since there is no co-existing plagioclase to saturate the clinopyroxene with regard to jadeite.

The P – T dependance of $K_D^{\text{ga+FeMg-min}}$ and the Al_2O_3 content in orthopyroxene coexisting with garnet, can also be used to interpret the chemical zoning of co-existing minerals

with regard to changing P – T conditions. In almost all the eclogites examined here, zoning of the ferromagnesian minerals is a common feature. The zoning is most prominent in the garnets, but zoning is also observed in the other ferromagnesian minerals. The most common type of zoning, which occur in the Sunnfjord and parts of the Nordfjord area, is that in which the FeO/MgO ratio in clinopyroxene and phengite increases from core to rim, and the same ratio in the coexisting garnet, and thus the $K_D^{\text{ga+cpx}}(\text{FeO/MgO})$ decreases in the same direction. In the coexisting orthopyroxene, the Al_2O_3 content increases slightly from core to rim. According to experimental studies this reflects an increase in both T and P , from core to rim. The reversed zoning is observed in the NW parts of the gneiss region (Fig. 1), except that the Al_2O_3 content in orthopyroxene increases strongly from core to rim. This zoning reflects a decrease in both T and P . This reversed zoning is also observed in the outermost rim of normal zoned minerals. In metamorphic rocks, however, only the rims of adjacent grains can be said to represent equilibrium conditions. Whether or not cores of coexisting minerals were in equilibrium with each other at an early stage of the metamorphism is often hard to evaluate. In the cases where, for example, clinopyroxene occurs as inclusions in the garnet core, this equilibrium seems to be obvious. In these cases $K_D^{\text{ga+cpx}}(\text{core})$ is constant, regardless of whether one uses analyses of cores of separate grains, or analyses of the inclusions and the adjacent garnet core. In these rocks $K_D(\text{core})$ should give P – T conditions appropriate to an earlier stage of the metamorphism. A good example of this, taken from an eclogite with prograde zoned minerals, is as follows (sample IB12, Nordfjord):

$$K_D^{\text{ga+cpx}}(\text{core}) = 8.6; K_D^{\text{ga+cpx}}(\text{incl}) = 8.6; K_D^{\text{ga+cpx}}(\text{rim}) = 6.8$$

This very clearly shows that the $K_D(\text{incl})$, which is taken close to the garnet core, gives the same K_D as the $K_D(\text{core})$, while $K_D(\text{rim})$ of adjacent grains gives the lowest value. The Jd -content of the clinopyroxene is rather constant (43%), and this gives the following temperatures and pressures: core and inclusion: 645 °C, 15.0 kbar; rim: 700 °C, 16.0 kbar. This suggests that the minerals grew during an increase in both P and T , that is, prograde metamorphism. In other cases, however, amphibole and/or phengite, rather than clinopyroxene, occur as inclusions in the garnet core. The garnet cores were thus not obviously in equilibrium with a clinopyroxene, but clearly coexisted with amphibole and/or phengite. This is commonly the case in the southernmost part of the area (Fig. 1). Therefore one should not use $K_D^{\text{ga+cpx}}(\text{core})$ in such cases, but rather $K_D^{\text{ga+ph}}(\text{core})$. A more detailed discussion of this problem is given elsewhere (E. J. K. and Råheim, in preparation).

The calculated P – T conditions define a path of metamorphic evolution for the Norwegian gneiss eclogites (Fig. 2). The prograde part of this curve extends from ~ 8 kbar, 300 °C to ~ 22 kbar, 800 °C. This is consistent with the trend for formation of eclogites given by Råheim and Green²².

From about 800 °C there is a drop in pressure and temperature which defines the retrograde trend. From Fig. 2 it is further evident that normal zoning occurs up to 700–750 °C. Above that temperature reversed zoning occurs.

The normal zoning of the minerals is interpreted as the result of crystal growth during prograde metamorphism; the inner parts of the mineral grains failed to re-equilibrate during the growth^{14,22}. The normal zoning could thus be denoted prograde zoning.

At a certain temperature, the diffusion rates will be high enough to homogenise the minerals, and thus wipe out the prograde zoning. By cooling and uplift, the rims of adjacent grains will continue to re-equilibrate by diffusion until the system again reaches the actual threshold temperature for diffusion. Good evidence for this is recorded in the normal (prograde) zoned minerals that show a thin zone of reversed (retrograde) zoning at the rims. Råheim and Green²² also describe these features, and they reach the same conclusions.

Fig. 2 Pressure and temperature calculations, based on co-existing mineral pairs from West Norwegian gneiss eclogites, define a prograde trend from ~ 300 °C, 8 kbar to ~ 800 °C, 22 kbar (I), and a retrograde trend from ~ 800 °C, 22 kbar to ~ 700 °C, 5 kbar (II). 1, 2, Melting curves for muscovite granite with excess H_2O , and dry muscovite granite, respectively²⁵. 3, Albite $\rightleftharpoons$ jadeite + quartz²⁰. 4, Eclogite $\rightleftharpoons$ granulite transition²³. 5, 6, 7, Kyanite/andalusite: andalusite/sillimanite and kyanite/sillimanite transitions, respectively^{26,27}.

Table 1 Mineral zoning (K_D^{ss+cpx}) and calculated pressure-temperature conditions in orthopyroxene-free and orthopyroxene-bearing eclogites

	Nordfjord, prograde		Sunnmøre, retrograde	
	Opx-bearing	Opx-free	Opx-bearing	Opx-free
$K_D^{(core)}$	19.0	15.7	5.0	5.0
$P: T_{(core)}$	10.2 kbar, 480 °C	9.6 kbar, 505 °C	22.3 kbar, 825 °C	19.3 kbar, 790 °C
$K_D^{(rim)}$	6.8	6.6	5.2	—
$P: T_{(rim)}$	23.0 kbar, 750 °C	17.6 kbar, 720 °C	6.6 kbar, 700 °C	—

The appearance of the secondary granulite facies assemblage orthopyroxene + plagioclase in the rocks showing retrograde zoning reflects the retrograde trend entering the granulite facies stability field²³ (Fig. 2). The very strong symplectitisation of primary omphacite in these rocks also suggests strongly decreasing pressure. Mysen and Griffin²⁴, however, give a more detailed discussion of this problem. The regional minimum K_D^{ss+cpz} (Fig. 1), and thus the P - T pattern (Fig. 2) indicates an increase in maximum P and T from south to north-west.

It is also of interest to point out the similarities in mineral zoning, K_D^{ss+cpz} , and thus the calculated P - T conditions, between orthopyroxene-bearing and orthopyroxene-free eclogites from the same areas. This is consistent both in the prograde and in the retrograde areas (Table 1).

Bearing in mind that the Jd -contents of clinopyroxenes in these eclogites only give minimum P - T values, both the zoning of the minerals (recorded in K_D variation from core to rim), and the minimum K_D values strongly indicate the same metamorphic history for these two types of eclogites.

The P - T path shown in Fig. 2 is consistent with that expected for regional metamorphic terranes now exposed at the surface; first a prograde (burial and heating) and then a retrograde (uplift and cooling) history. It is also evident from Fig. 2 that the rocks from a relative high dP/dT were exposed to a lower dP/dT environment. Thus there must have been a considerable change in the regional geothermal gradient in the area during the metamorphic cycle.

During subduction of a cold slab, the isotherms will be depressed. Once the subduction ceases, and during the succeeding uplift, the anomalous isothermal pattern will be smoothened out, and the area restored to its normal geothermal gradient. The subduction + uplift process can thus explain the metamorphic cycle that is reflected in the zoning of the minerals of the west Norwegian eclogites.

As mentioned above, datings suggest that eclogites are parts of a continental mass metamorphosed 1,700 Myr BP, and later disturbed at ~1,000 and ~400 Myr BP. The convergent margins in this case must therefore have been of a continent-continent collision type, followed by a subduction of one of the continents under the other. Before a continent-continent collision, a subduction of oceanic crust under one of the continents would be expected, thus producing an Andes type orogenic belt. This will cause an increase in the thickness of the continental crust at the continental margin. The continental-

continental collision itself will also lead to a further thickening of the continental crusts. By a further subduction of one of the continents on the cold side of an Andes type mountain chain, the subducted continental slab may be exposed to depths of 80–100 km without significant melting (Fig. 2). This type of orogene-forming process will also lead to a high degree of isostatic disequilibrium. This implies a rapid isostatic uplift, high reliefs and a rapid erosion rate, that is, a relatively rapid decrease in pressure.

The present data give good evidence to suggesting that plate tectonics were active as early as 1,850–1,700 Myr ago. Evidence for the existence of an early (> 1,850 Myr ago) proto-Atlantic ocean of the Pacific type is also found further north along the same coastal margin in the Lofoten-Vesterålen area (E. J. K., in preparation).

I conclude that all the eclogites examined here can represent crustal rocks metamorphosed *in situ* during subduction of a continental crust to depths of 65–80 km. At these depths some mantle material may have been picked up, but the separation and recognition of the mantle derived rocks is not straightforward at present.

I wish to thank Dr W. L. Griffin for constructive criticism. This work was supported by grants from Norges Almenvitenskapelige Forskningsråd.

Conformational change theory for auxin structure-activity relationships

T. M. Kaethner

Biophysics Unit, ARC Institute of Animal Physiology, Babraham, Cambridge, UK

An hypothesis is advanced that the hormonal activity attributable to the heterogeneous group of plant growth compounds called auxins is a direct result of the ability of the bound auxin to undergo a simultaneous conformational change or reorientation with the receptor, while in the binding site.

THE structure of the plant growth hormone indol-3-yl-acetic acid (IAA, natural auxin) was established in 1934¹, and considerable effort has been devoted to elucidation of molecular requirements regarding auxin structure and hormonal activity^{2–6}, but as yet no theory has predicted comprehensively the relationship between molecular structure and hormonal activity.

Fig. 1 Cross-sectional representation of the proposed IAA-receptor site, showing the outline of IAA (broken lines) bound in the recognition conformation. Two electropositive regions (i) and (ii) are bisected by the plane of the section; region (iii) is electro-positive, whereas (iv) is electronegative. The cross-hatching for region (v) represents areas of hydrophobic interaction with one or both sides of the receptor cleft, which has proportions resembling those of a canopied crib.

In the hypothesis described here, the hormonal activity of the heterogeneous group of compounds called auxins⁷ is attributed to the ability of the bound ligand to undergo a simultaneous conformational change or reorientation with its receptor while in the binding site of that receptor. I propose that there is a single site for primary auxin action, possessing five regions of major discriminatory significance with regard to auxin binding (Fig. 1): (i) and (ii) are two electropositive regions, possibly paired, and are responsible for recognition of the carboxyl or other acidic group of the auxin; they also show the essential conformational change relative to the ligand and remainder of the receptor; (iii), a third adjacent electropositive region; (iv), an electronegative region on, or comprising the 'floor' of, the receptor site, normally responsible for hydrogen-bonding with the pyrrole nitrogen region of IAA; and (v) an hydrophobic cleft, interacting chiefly with the benzene ring region of the indole nucleus, rather than the entire ring. Thus the site has proportions resembling a canopied crib, three electropositive regions comprising the canopy, a fourth electronegative region delimiting the 'floor', with the hydrophobic regions as the sides. The site is open for auxin recognition and binding at the 'top' and 'front'.

Recognition of IAA by the electropositive regions (i) and (ii), and subsequent binding in the site, occur with the side chain of IAA in the plane of the ring such that the oxygens of the carboxyl group lie astride the ring plane, directed over the hydrogen of carbon 4 of the indole ring; this is termed the recognition conformation (Fig. 2). The bound IAA molecule now undergoes a simultaneous conformational change with the receptor; while still interacting with regions (i) and (ii) of the site, the carboxyl group and side chain of IAA assume a position perpendicular to the plane of the indole ring, such that the oxygens of the carboxyl group are aligned so as to be co-linear with an imaginary line joining carbon 3 and nitrogen of the indole nucleus; this is termed the modulation conformation (Fig. 2).

Thus, competence as an auxin requires adoption of the essentially planar recognition conformation, and an ability to move in concert with the receptor to the modulation conformation. The obvious corollary is that molecules which can bind in the site, but which are unable to show a simultaneous conformational change with the receptor, will not

be active as auxins. By occupying the site ineffectually, such compounds will antagonise auxin action; the more potent auxin antagonists are proposed to have these properties of high affinity, zero capacity auxins.

To relate structural analogues of IAA back to this model, primary emphasis must be placed on the orientation of the side chain and carboxyl group of the test compound. These must be aligned so that their angle of inclination coincides as nearly as possible with that of IAA in its recognition conformation. Figures 3 and 5 illustrate this. With this reference point established, molecular comparisons among the whole family of auxins can be made, according to the simplistic approach that the role of a synthetic auxin is to reproduce as best as possible the features of IAA, especially its dimensions.

The exceptional molecular structure of auxins of the arylcarboxylic acid type necessitates elaborated discussion of their structure-activity relationships, but the activities of other synthetic auxins (including dithiocarbamates and acyclic analogues) can be assessed largely in terms of three factors: (1) hindrance to side chain mobility resulting from *ortho* substitutions about the side chain; (2) hindrance to side chain mobility resulting from substitutions on the side chain, and (3) hindrance to binding due to substituents in positions corresponding to substitutions on C₇, C_{7a}, or N₁ of IAA.

Factors (1) and (2) relate to the ability of auxins to show the required conformational change, that is their capacity to function; factor (1) is best exemplified by the influence of di-*ortho* substitutions in phenoxyacetic acid derivatives, where hormonal activity is markedly reduced⁸⁻¹⁰, or lost⁹⁻¹¹

Fig. 2 IAA, with side chain in the recognition conformation (a). Oxygens are astride the ring plane. In the modulation conformation (b) the side chain moves to a position perpendicular to the ring plane, and the carboxyl group realigns as shown.

Fig. 3 Comparison of the molecular dimensions of IAA (broken lines) and 3,5-dichlorophenoxyacetic acid (solid lines), both in the recognition conformation.

unless the size of one of the *ortho* substituents does not exceed that of fluorine¹⁰. The greatly diminished activities for 2-methyl-IAA¹²⁻¹⁴, 8-chloronaphth-1-yl-acetic acid^{15,16} and 1,3-dichloronaphth-2-yloxy-acetic acid¹⁷, by comparison with their unsubstituted parent acids, further illustrate the point. The variable behaviour of naphth-1-yloxy-acetic acid in different bioassays⁴ is also explained on the basis of the rotational degeneracy of the side chain; extensive side chain movement is impeded by the *ortho* hydrogen at carbon 2 of the ring, so that any capacity for hormonal activity may be reduced to zero, with antagonistic properties arising^{18,19}, according to the degree of movement demanded by the receptor site in question. The same does not apply to the structural isomer naphth-2-yloxy-acetic acid, an auxin of moderate activity^{8,17-19}; the relocation of its side chain on the ring leaves the required movement sterically unhindered.

Factor (2) relates especially to optical isomerism in auxins. Two compounds differing only in their arrangement of groups around an asymmetric carbon in the side chain can have profoundly different activities as auxins. Not surprisingly, the absolute configuration of such enantiomers and their respective hormonal activities are very closely correlated; in all but a very few instances (discussed in detail in ref. 20) enantiomers with the *D*-configuration possess higher auxin activity than the corresponding *L*-forms, while the *L*-forms are often inactive as auxins or are auxin antagonists⁵.

I propose that the basis of the differing properties of enantiomers is a single fundamental feature—the need to retain the ability to undergo a conformational change if capacity as an auxin is to be retained. Adsorption into the receptor site immediately imparts a sidedness on the auxin molecule, hitherto non-existent in most cases. Because the conformational change of the receptor is specifically directional, that of the ligand must be also, and movement of the carboxyl group to the face of the indole ring as shown in Fig. 2 is proposed as the only side chain movement able to confer hormonal activity. The ability of the side chain to move to the 'back' face (as depicted) is of no consequence to activity. Thus the contrasting steric locations of substituents in enantiomer pairs and the consequent effects on the ability of the side chain to move between recognition and modulation conformations is reflected in the general trends relating absolute configuration and hormonal activity. Side chain substituents in the *L*-configuration introduce intra-molecular steric hindrance to side chain movement, reducing hormonal activity and often imparting antagonistic properties. Generally the stereo-relationships imposed by the absolute *D*-configuration prohibit such intramolecular

effects. Methyl substituents on the side chain of auxins in the *D*-configuration may, however, reduce unfavourable electrostatic interactions with the electropositive region (iii) of the receptor site, resulting in increased affinity between ligand and receptor in the case of weak auxins⁹.

Data tabulated for the activities of all mono-, di- and tri-chlorophenoxyacetic acids¹¹ not only illustrate factor (1), but (3) also. All compounds displaying zero activity in the particular bioassays used by Leaper and Bishop possess either di-*ortho* substitution, or are unable, by face reversal (rotation about the bond linking the side chain to ring), to avoid placing a substituent in locations analogous to those which would be adopted in the site by substituents on C₇, C_{7a} or N₁ of IAA (di-*meta* phenoxyacetic acid derivatives, Fig 3); the reduced activities of 7-chloro-IAA¹³, N₁-methyl-IAA^{12,13}, 4-chloro- and 5-chloro-naphth-2-yloxyacetic acids¹⁷, relative to the unsubstituted parent acids, is also explained on the basis that the substitutions introduce novel interactions with the 'floor' of the receptor site, thereby reducing binding affinity.

Auxins of the arylcarboxylic acid type lack a spacing atom between the carboxyl group and ring structure, so that a conformational change of the type proposed for other auxins is not possible. Instead, arylcarboxylic auxins are proposed to show a molecular reorientation in conjunction with the conformational change of the receptor. As usual, recognition and binding occur with the oxygens of the carboxyl group astride the ring plane. Once in the site the entire molecule is envisaged to tilt through approximately 45° relative to the ring plane at recognition 'conformation', about an horizontal axis passing through ring

Fig. 4 2,6-dichlorobenzoic acid, with the alignment of the carboxyl group determining molecular orientation for the recognition 'conformation' (top). A modulation 'conformation' (below) equivalent to that adopted by IAA is assumed by partial rotation of the molecule about a horizontal axis passing through the centre of the ring.

R393

carbons 2 and 5; in this manner the molecule assumes an equivalent modulation conformation (Fig. 4). This theory would endorse the two salient features of Veldstra's conclusions²¹ concerning benzoic acid structure-activity relationships: a non-flat structure, with the carboxyl group oxygens astride the ring plane, is essential for binding; all other requirements with respect to substituents, including the di-*ortho* substitutions responsible for the non-flat structure, are suggestive that absence of intermolecular hindrances to binding in the receptor site is critical, rather than a requirement for the presence of specific unsubstituted locations on the ring for binding.

There is insufficient evidence to make further conclusions about structural requirements for activity in benzoic acid derivatives. The observation that *para* substituents on benzoic acid exceeding the size of fluorine are incompatible with activity²¹ would seem to require the proviso that consideration also be given to possible stabilisation of charged resonance forms of the ligand. Thus the inactivity of *para* chlorinated benzoic acids²¹ and data on their potency as antagonists of auxin action²²⁻²⁴ suggest that such derivatives are accepted into the site, but are unable to show a re-orientation in concert with the receptor conformation change; presumably steric interaction between the *para* chloro group and the 'floor' of the site prevents the required reorientation from occurring. The *modus operandi* of 4-amino-3,5,6-trichloropicolinic acid as a hormone will resemble that of the benzoic acids, yet despite the presence of a chloro substituent *para* to the carboxyl group, this compound can show hormonal activity exceeding that of IAA²⁵. It is thought that resonance stabilisation of charges could influence the activity of this compound in two relevant ways; first, molecular dimensions may be altered to render it sufficiently different from *para* chlorinated benzoic acids; and second, the positively charged amino group is able to assume a location in the binding site analogous with that of the pyrrole nitrogen of the indole ring of IAA, so that favourable interaction with the proposed electronegative region (iv) might reduce hindrance to the '*para*' chlorine substituent during the molecular re-orientation required for activity.

Figure 5 illustrates an empirical method of approximately summarising the maximum ligand dimensions permissible for binding under the canopy region of the site. The expected variation amongst receptor sites (tissue-specific and species-specific) will prevent adoption of a single critical dimension universally applicable to auxins for the distance between 'top' of the ligand carboxyl group (in the recognition conformation) and the lowest molecular extremity. The values chosen for Fig. 5, however, exclude such diverse inactive auxin analogues as *trans*-cinnamic acid²⁶, 2,6-dibromo-, 2,6-diiodo- and 2,6-dimethoxy-benzoic acids³, 9-anthracenecarboxylic acid²⁷ and indol-3-yl-carboxylic acid^{2,12}.

True antagonism to auxin action (as opposed to general metabolic inhibition) is considered, on this hypothesis, to be due to two general types of compounds. One category can be regarded as high affinity, low capacity auxins, as they occupy the site but are unable to show a conformational change or reorientation with the receptor. Examples of this type are L(-)- α -(2-methyl-4-chlorophenoxy)-propionic acid^{28,29}, 4-chloro- and 2,4-dichlorobenzoic acid^{23,24}, 2,6-dichlorophenoxyacetic acid³⁰, and auxins with isobutyric acid side chains³. A second class of antagonists have the properties of low affinity, high capacity auxins; although side chain flexibility leaves such molecules with the capacity to function as auxins, the nature of the remainder of the molecule reduces affinity for the receptor site and these antagonists compete with auxins for receptor regions (i) and (ii). Examples of this second type are 3,5-dichlorophenoxyacetic acid, and phenoxyacetic acid and its 2-halogen derivatives³. Åberg's discussion of antagonism of potent

auxin action by weak auxins would be viewed as this second form of antagonism. Gradations between these two classes of antagonists will occur.

The hormonal activities attributable to L(-)- α -(indol-3-yl)-propionic acid³¹⁻³³, α -(indol-3-yl)-isobutyric acid^{3,33}, and L(-)- α -(benzothien-3-yl)-propionic acid³⁴ remain unexplained by this theory. Molecular models of these compounds suggest their side chain movement to the modulation conformation is not possible, and the theory would predict antagonistic properties for them; indeed, this is the case for α -(indol-3-yl)-isobutyric acid³⁵ and L(-)- α -(benzothien-3-yl)-propionic acid³⁴ in some bioassays. High auxin activity and strong antagonism, however, are viewed as mutually exclusive features, and it is not without precedent to comment that these compounds deserve more rigorous investigation^{3,6}. All structures closely resemble that of the natural auxin IAA, and the contradictory results presently available for them may reflect metabolic conversions to active forms within some test tissues.

Fig. 5 An empirical method of approximately summarising the maximum ligand dimensions permissible for binding under the 'canopy' region of the receptor site (solid lines). Measurements are taken from the top of the carboxyl group when side chain (if present) and carboxyl group, in the recognition conformation, are aligned so as to coincide with the corresponding regions of IAA in its recognition conformation (IAA ----; 2,6-dichlorobenzoic acid - - - - -).

When this conformational change model for auxin action is discussed within the context of former theories of auxin structure-activity relationships, it is seen that it represents a rationalisation and extension of previous concepts. First, molecular significance can be attached to the five structural features characterising the many synthetic auxins known by 1938². A ring system provides the planarity to fit the cleft, an hydrophobic core for interactions with appropriate regions on the receptor site, and in the case of IAA, the molecular complexity to facilitate hydrogen bonding through the indole nitrogen region. Double bonds in the nucleus (or minimally, one double bond with the side chain attached to it³⁶) permit adoption of a recognition conformation with the side chain in the plane of the ring and a modulation conformation with the side chain perpendicular to the plane of the ring. A side chain arising from the ring nucleus provides the molecular flexibility required for simultaneous conformational changes with the receptor. A carboxyl group (or other acidic function) on the side chain is essential for auxin recognition by sites (i) and (ii); the stipulation that the carboxyl group be separated by one atom from the ring again relates to the need for molecular flexibility if hormonal activity is to be retained. The observation that a particular space relation between carboxyl group and ring was required for activity reflects the necessity for side chain conformational degeneracy so that the carboxyl group can move between two specific spatial locations defined by the extent of movement of the recognition

regions (i) and (ii) of the receptor as this shows its conformational change.

Furthermore, the proposed recognition conformation apparently coincides with the active auxin form suggested by Jönsson⁴, while the modulation conformation is equivalent to the active form proposed by Veldstra³. The premises of the two-point attachment theory³⁷ and three-point attachment and α -hydrogen theory³⁸ are encompassed by the hypothesis that side chain conformational changes are essential for auxin activity. The 5.5 Å (0.55 nm) charge separation theory³⁹ is a rigid hypothesis expressing the possible relevance of charged regions of auxins to receptor site binding; apart from the specific case of IAA, and the general requirement for an acid group on the ligand, it has little in common with this theory.

That auxin action entails more than a simple binding at a site has been intimated by others. Veldstra³ considered that auxins should possess "a capacity to cause a specific physiological response when fixed to the receptor (in dynamic equilibrium with free molecules!)". Similarly, discussing the influence of some alkyl side chain substituents on hormonal activity, Fredga and Åberg⁵ concluded that "the large substituent in some way hinders the side chain of the molecule from assuming the position leading to auxin activity". Unwittingly, both comments predict this hypothesis, that capacity to function as an auxin requires an ability to undergo a simultaneous conformational change or reorientation with the receptor.

An understanding of the biochemical significance of the proposed conformational change induced in the receptor by auxin binding must await characterisation of the site of auxin action. The nature of this conformational change theory of auxin structure-activity relationships is, however, compatible with current theories on the biochemical basis of auxin action, and not exclusively applicable to one only.

I thank Dr A. D. Bangham and Professors Harry Yamamoto and L. J. Audus for constructive criticism. I

am the recipient of a United Kingdom Award under the Commonwealth Scholarship and Fellowship Plan.

Structural comparison of the major envelope glycoproteins (gp70) from 35 different murine type C viruses and free gp70 expressed at various anatomical sites in the mouse showed that the gp70s are polymorphic products of a large multi-gene family encoding viral and differentiation antigens. Different proviruses are expressed in cells following distinct pathways of differentiation. When the various gp70s are grouped according to primary structure they fall naturally into viral host range classes, confirming the suspicion that C-type viral tropism is largely determined by the nature of the gp70 product expressed.

POLYMORPHISM of certain viral proteins is well known and often forms the basis for the serological classification and subdivision of

antigenically related viruses¹⁻³. Viral polymorphism probably reflects the response of specific viral genes to selective pressure, and as for the influenza viruses, may influence the dynamics of the host-parasite relationship³. When, however, one considers the murine C-type viruses, the issue of polymorphism takes on a unique significance in that these agents may spend at least part of their life cycle as proviruses integrated into the host chromosomes where they may be inherited according to mendelian expectations⁴⁻⁶. One or more of the proviral genes may be expressed at certain sites of differentiation, often in the absence of complete virus production⁶⁻⁹. Insofar as expression of the provirus is regulated during cellular differentiation, its gene products may be considered among the differentiation antigens of the mouse¹⁰. There are two important questions regarding polymorphism of C-type viral proteins as structural components of intact virus and cellular differentiation markers. The first question concerns whether the gene products are 'virus-like' with extensive divergence or more

'host-like', where even the products of the most polymorphic loci are relatively conserved. Second, we need to know whether different proviruses are expressed at different sites of differentiation, resulting in the presence of multiple subtypes of related viral proteins within a single animal.

Of the various gene products of endogenous C-type viruses, the major envelope glycoprotein gp70 is well suited for a study of polymorphism. This glycoprotein has a role in the host range, interference and neutralisation properties of the virus and carries the type-, group- and interspecies determinants which form the basis for viral subclassification. But a classification based on the functional properties of viral gp70 does not allow comparison at the molecular level and cannot be used in the absence of infectious viruses. Therefore, a more rigorous approach to the study of

Tryptic peptides of gp69, gp70 and gp45 are identical

Initial experiments were performed to determine the value of ^{125}I tryptic peptide analysis as a tool for structural comparison of related gp70s. One issue we needed to resolve concerned the possible presence of more than one gp70 in a given virus preparation, as was suggested by the early finding that Rauscher gp70 could be resolved into discrete bands with molecular sizes of 69,000 and 71,000 (refs 11, 12). If gp69 and gp71 were different gene products this would obviously complicate a structural study of polymorphism. In addition, we studied a protein with molecular weight of 45,000 which is precipitable by anti-gp70 antisera and is found in certain virus preparations. In Fig. 1 the tryptic peptide

Fig. 1 Comparison of the tyrosine-containing tryptic peptides of Moloney virus gp71, gp69 and gp45. Moloney virus gp69/71 was purified by phosphocellulose chromatography and was a gift from Dr S. Kennel of Oak Ridge Laboratories. The protein (10 μg) was radiolabeled with ^{125}I (Amersham, specific activity about 15 $\text{mCi } \mu\text{g}^{-1}$) to high specific activity by the chloramine T method¹³ in the presence of either 0.5% NP40 in 0.5 M phosphate buffer (a-c) or 1% SDS in 8 M urea (d-f). Gp71, gp69 and gp45 were then separated by SDS-PAGE¹⁴, the gels were sliced and the slices containing the radioactive proteins were pooled and placed in 10% acetic acid. The slices were washed extensively with 10% methanol to remove SDS, dried with a heat lamp, and placed in a solution of 50 $\mu\text{g ml}^{-1}$ trypsin (Worthington, 27 IU mg^{-1}) in 0.05 M NH_4HCO_3 buffer (pH 8.0). The slices were incubated overnight at 37 °C, after which the solution was removed and lyophilized. The tryptic digests were then analysed on two-dimensional peptide maps¹⁵. The samples were dissolved in 20 μl buffer I (acetic acid-formic acid-water, 15:5:80) and 2–5 μl was spotted on to 10 cm $\times$ 10 cm cellulose-coated TLC plates (EM Laboratories). The samples were then electrophoresed at 1 kV for approx. 30 min, dried and chromatographed in a second plane using buffer II (butanol-pyridine-acetic acid-water, 32:5:25:5:20). The plates were then dried and analysed by autoradiography using Kodak RP-X-ray film. a-c, gp71, 69 and 45, respectively, radiolabeled in NP40; d-f, GP71, 69 and 45 radiolabeled in the presence of 1% SDS and 8 M urea.

polymorphism requires the use of techniques allowing direct comparison of primary structure. We report our comparison of the primary structure of 27 different virion-associated gp70 molecules and gp70 isolated from the sera and seminal fluid of nine different strains of mice. Based on the tyrosine-containing tryptic peptides of these gp70s, the C-type viruses of murine origin can be divided into several groups with varied degrees of relatedness. Polymorphism exists within each of these groups. Compared to viruses recently isolated from inbred or from feral mouse populations, the gp70s of the laboratory-derived murine viruses vary extensively in structure. The structure of the gp70 found free in the serum of all mice tested is relatively conserved and seems to be the product of the same or similar xenotropic virus gene regardless of how many other proviruses the mouse may harbour. The provirus coding for the serum protein is distinct from that coding for the genital tract gp70 and thus unique proviruses are expressed at different sites of differentiation.

analyses of gp71, gp69 and gp45 present in a preparation of purified Moloney virus gp70 are shown. Figure 1a-c shows that the tyrosine-containing peptides of these three proteins are identical. Another question answered in this experiment is the extent to which the carbohydrate portion of the molecule influences the resultant tryptic map. It is estimated that 32% of the mass of gp70 is carbohydrate, whereas carbohydrate is only 6–9% of gp45¹⁶. Because the tryptic maps of gp69, gp71 and gp45 are identical, it is apparent that the mass of carbohydrate does not greatly influence our analyses and this is because the glycopeptides do not migrate in the apolar solvent used here for chromatography (our unpublished results). Another methodological question concerned the extent to which conformation of the molecule influenced radioiodination and the subsequent peptide map. Figure 1a-c shows the tryptic peptides of the proteins iodinated in the presence of NP40 (0.5%) and 0.05 M sodium phosphate buffer; in Fig. 1d-e these proteins are radioiodinated in the presence of 1% SDS and 8 M urea.

Fig. 2 Comparison of the tyrosine-containing tryptic peptides of gp70 isolated from several endogenous and exogenous ecotropic (mouse-tropic) viruses. *a*, Wild mouse 292M; *b*, wild mouse 4070M; *c*, BALB/c B-tropic; *d*, AKR; *e*, R-MuLV; *f*, F-MuLV. Rauscher virus, produced in chronically infected JLSV-9 cells, was obtained from Dr Jack Gruber of the Resources branch of the NCI. SC-1 cells producing AKR virus (AKV-1) were obtained from Drs W. Rowe and J. Hartley and virus pools were prepared from the third and fourth subculture in our laboratory. Friend virus¹⁷ was a gift of Dr W. Parks. B-tropic virus (no. 138) was isolated from a 3-methylcholanthrene-induced tumour of a BALB/c mouse. The no. 138 virus is completely restricted in FV-1ⁿ cells even at high multiplicity of infection. Pools were prepared from the third to fifth tissue culture passage for use in this study. The origin and clonal purification of wild mouse ecotropic viruses (1504M, 292M, 4070M, 1740M) have been described¹⁸. Enriched fractions of gp70 were obtained from virus isolates by immunoaffinity chromatography as described¹⁹ with several modifications. Monospecific goat antisera to Rauscher virus gp70 (G230) was used as the source of antibody. Proteins were eluted from the affinity column with a 0–2 M TCA gradient at neutral pH as suggested²⁰. The majority of non-specific protein came off the column from 0 to 0.75 M TCA. Gp70 was eluted from the column at 1–1.5 M TCA. After dialysis against phosphate-buffered saline, gp70 from all isolates retained antigenicity and remained stable for several months at –20 °C. After dialysis, the gp70 fractions were radioiodinated as in Fig. 1 and direct precipitates were performed with G230 antiserum. The immune precipitates were then electrophoresed on SDS-PAGE and treated for peptide mapping as described in Fig. 1.

Changes in the intensity of certain spots have occurred, but the total pattern is the same. This suggests that conformation of the gp70 molecule may influence the extent of iodination of certain peptides but all peptides are labelled even under relatively mild conditions.

The virion-associated gp70s can be divided into groups

Based on tryptic peptide analyses of 27 virion-associated gp70s, the following conclusions are drawn: (1) The gp70s of the murine viruses which both grow in and infect mouse cells (ecotropic viruses) can be divided into several divergent groups. This point is illustrated in Fig. 2, in which the tryptic peptides of 6 endogenous and exogenous ecotropic viruses are shown. Overall, the gp70s of the various wild-type ecotropic (*a–d*) viruses are more related to each other than to the FMR (*b, f*, Fig. 1*a*) viruses. The gp70s of the ecotropic viruses of wild mice (Fig. 2*a, b*) form a closely related group, distinct in structure from the prototype AKR viruses (*d*). The gp70s of FMR viruses, Friend, (Fig. 2*f*), Rauscher (Fig. 2*e*) and Moloney (Fig. 1) are divergent from each other and the other ecotropic viruses, possibly as the result of a recombinant origin. These data indicate that extensive diversity exists from one group to another in spite of the fact that ecotropic gp70s share the common property of facilitating entry of their respective viruses into mouse cells, but not cells of other species. (2) The gp70s of the endogenous viruses which are produced by mouse cells, but can only infect cells of other species (xenotropic viruses), form two groups, one of which is closely related to the gp70s of viruses which can infect both mouse cells and cells of other species (amphotropic). In Fig. 3, the tryptic peptides of several xenotropic virus gp70s and an amphotropic virus gp70 are compared. BALB/c, AKR and NIH xenotropic gp70s are closely related to one another and to the amphotropic gp70, but are distinct from the NZB xenotropic virus gp70. We interpret the differences within the large group of xenotropic gp70s (as well as the gp70s of C₃H and NZW, not shown) as polymorphism within a group. The gp70 of the NZB xenotropic virus is divergent to the point that we place it along with (NZB × NZW) F₁ (not shown) into a separate group of xeno-

tropic virus. These findings are in general agreement with serological studies of others²³. (3) The gp70s of amphotropic wild mouse viruses form a single highly conserved group closely related to one of the xenotropic groups (Fig. 3). The structure of the amphotropic gp70s will be completely described in a separate report (Bryant *et al.*, in preparation).

To determine whether the cell in which the viruses were propagated influenced our results, we compared the structure of the gp70s of three different amphotropic viruses, each of which had been grown in mouse, rabbit and mink cells. The gp70s were identical irrespective of in which cells the viruses were grown. This suggests that host cell modification of gp70 is not a significant variable in our studies.

The serum gp70 of laboratory and wild mice is homologous to the NZB xenotropic virus gp70

Large amounts of gp70 are present in the serum of many strains of mice in the absence of intact viruses⁷. To determine which provirus(es) encode serum gp70 we compared the tryptic peptides of gp70 isolated from the serum of several strains of mice. In Fig. 4, the tryptic peptides of virion-associated NZB gp70 (*a*) and 5 gp70s isolated from sera of different murine strains (*b–f*) are shown. The data indicate that the serum gp70s are members of a highly conserved group, all of which are closely related to the NZB xenotropic virus gp70. Additionally, NZW and two wild mouse serum gp70s had the same structure (data not shown). Thus, the serum gp70 of all mice we have tested is probably a partial expression of a single provirus, which is expressed as complete virus only in the NZB and (NZB × NZW)F₁ mice. In so far as that part of the provirus coding for serum gp70 is concerned, there has been little divergence and it appears to behave like a moderately polymorphic murine gene. These structural studies support the data of Stephenson and Aaronson in which it was shown that serologically the serum gp70 resembled that of the NZB xenotropic virus²³.

Fig. 3 Comparison of the tyrosine-containing tryptic peptides of several xenotropic virus gp70s and amphotropic virus gp70. *a*, BALB/c; *b*, AKR; *c*, 1504A; *d*, NIH; *e*, NZB. Xenotropic virus isolates were obtained from spleen lymphocytes or from lung fibroblasts of normal AKR, NZB, (NZB x NZW) F_1 , C $_3$ H and NZW mice by co-cultivation with rabbit endothelial cells. The rabbit endothelial cells were derived from the pulmonary vein or from the vena cava of a New Zealand rabbit. For isolation of xenotropic viruses, endothelial cells were used from the fifth to twentieth tissue culture passages. Virus replication was monitored by RNA-dependent DNA polymerase assays. All xenotropic virus isolates were characterised by their ability to rescue the murine sarcoma virus genome from MSV-transformed non-producer rat cells (1255-B7), by radioimmune assays for p30, and by the lack of replication in secondary mouse fibroblasts of FV-1 ^{B} or FV-1 ^{b} strains. In all cases, xenotropic virus recovered from either spleen or lung yielded the same result in our analyses. The cloned amphotropic isolate (1504A) was prepared as described¹⁸. Amphotropic viruses have the combined host range characteristics of both mouse-tropic and xenotropic

Distinct proviruses are expressed at different sites of differentiation

To study whether different proviruses are expressed at different sites of differentiation we compared the structure of gp70s isolated from different anatomical sites in the same mouse. Figure 5 shows the tryptic peptides of the gp70 isolated from the serum and seminal fluid of 129 mice. Clearly the two proteins are distinct. The serum protein resembles gp70 of the NZB xenotropic virus whereas the seminal fluid protein is like the FMR group in

Fig. 4 Comparison of the tryptic peptides of NZB virus gp70 with the tryptic peptides of gp70s isolated from the serum of several strains of mice. *a*, NZB virus; *b*, NZB serum; *c*, (NZB x NZW) F_1 ; *d*, B x SB; *e*, AKR; *f*, MRL/L. Serum gp70s were isolated by immunoaffinity chromatography and treated for peptide map analysis essentially as described in Fig. 2. EDTA (10 mM) and EGTA (10 mM) were added to the sera prior to passage over the immunoaffinity column to prevent complement binding and reduce proteolysis. B x SB is a new recombinant inbred strain derived from a single (C57 B1/6 x SB/Le) F_1 cross with selection for the mutant satin (*sa*) and beige (*ba*) genes developed by Dr Edwin D. Murphy of Jackson Laboratories. MRL/L is a new recombinant inbred strain obtained from the twelfth generation of an inbred stock derived from strains LG, AKR, C $_3$ H and C57 B1/6, also developed by Dr Murphy. Analysis of the gp70 from the sera of wild mice from two separate populations (Lake Casitas and Bouquet Canyon²⁴) had similar homology to the NZB xenotropic virus gp70 (not shown).

viruses, but different interference and neutralisation specificities and are negative in the XC test^{18,21,22}. BALB/c (no. 435) and NIH Swiss (no. 436) xenotropic viruses were a gift of Drs Hino, Stephenson and Aaronson of NIH and their origin and purification have been described²³. Gp70s were isolated and analysed as described in Fig. 2. *f*, Composite of the major spots of the xenotropic and amphotropic virus gp70s, indicating the degree of interrelatedness between the molecules. Crosshatched areas, common to all; ○, common to amphotropic gp70 and to *a*, *b* and *d* (as well as C $_3$ H and NZW, not shown); ●, common to NIH and NZB; ○, common to NZB (and NZB x NZW F_1 , not shown).

Formulation for members of the multi-gene family

Table 1 summarises all the data presented above. All the virion, serum and tissue proteins on the diagram are immunologically related and thus can be considered expressions of a multigene family²⁶. Groups are represented as joined boxes which are spatially placed to indicate our estimation of the extent of interrelatedness between the groups. Based on our preliminary

Table 1 Summary diagram of the structural relationship between all virion- and non-virion-associated gp70s analysed

Joined boxes represent closely related groups and the spatial arrangement of these groups is intended to indicate intergroup relatedness. The gp70s found free in the epididymal fluid and on the surface of thymocytes are surrounded by broken lines and are placed according to their structural relatedness to virion-associated gp70s. W.M., wild mouse; C.A.S., Casitas trapping area; B.Q., Bouquet Canyon trapping area.

structural studies, the thymocyte-associated gp70 is placed in the xenotropic group. We are now doing the N-terminal sequence of a number of these gp70s to determine precisely the inter- and intra-group divergence.

Discussion

We show here that the various virion-associated and free serum gp70 molecules can be divided into groups. The extensive inter-group divergence of the FMR ecotropic murine viruses may be due to their unique origins but may also reflect recombinations during their laboratory history. By contrast, minimal divergence is seen among the members of groups of endogenous viruses very recently isolated from inbred or wild mice. Thus, given the opportunity for recombination and/or replication outside the host, oncornaviruses may diverge extensively. But, under mendelian restrictions members of each group remain relatively conserved, suggesting that selection operates at the level of the integrated provirus.

It is clear that the endogenous free or virion-associated gp70s are part of a multigene family of immunologically and structurally related proteins. An important question is: how many members does the family contain? We believe that the family may be extensive, but at present we can only give a lower limit for expression of at least five members within a given mouse. For example, in an AKR mouse there are two AKV genes, one AKR xenotropic virus gene, one gene for the serum gp70, and a gene for one of the proteins secreted into the male genital tract²⁵. This accounting does not include at least five additional gp70s expressed at other sites of differentiation¹⁰, as we have not yet

isolated these to determine if they differ from the known gp70s.

In the case of the endogenous AKR provirus, it has already been shown that two presumably identical genes (AKV-1 and AKV-2) have different genetic loci²⁷. But, in spite of the different loci, our recent studies with Hartley and Rowe have shown that the gp70s of viruses derived from AKV-1 and AKV-2 are identical. Thus with respect to the xenotropic proviruses, the question is whether they are also non-alleles or simply very polymorphic products of a single locus. Our results show that there are at least two loci for xenotropic proviruses in that in most mice a virus can be recovered from many tissues which has a gp70 distinct from that present in the serum of the same mouse. The provirus encoding the serum protein can be considered xenotropic in that in the exceptional strain (that is, NZB) when this gp70 becomes part of a virion, it confers xenotropic host range. In so far as the genes for the complete xenotropic viruses of different strains are concerned, our data do not allow us to distinguish between non-alleles against extensive polymorphism at a locus.

If we accept the assumption that the various endogenous proviruses are non-alleles, then a very interesting question concerning regulation of their expression emerges. Studies in our laboratory and Boyse's have already shown that in the mouse, gp70 is expressed only in cells following certain pathways of differentiation^{4,9}. Now the issue becomes whether at each site of differentiation the gp70 is the product of a different provirus. Although we cannot yet be precise about the answer, there are already some observations which suggest that at each site of differentiation one or more different proviruses are expressed. For example, as mentioned above, within a strain the serum and one of the genital tract gp70s have different tryptic peptides. In terms of neoplasia if the proviruses expressed at different sites of differentiation are not genotypically equivalent then one can begin to understand how expression of the viral genome at one site can have oncogenic consequences distinct from another. Regardless of to what extent we are dealing with polymorphism against multiple genes, it is already clear that the study of endogenously expressed gp70 can give important insights into the extent and perhaps mechanisms of divergence of a well-defined murine glycoprotein. The uniqueness of the situation, of course, stems from the fact that because of the extrachromosomal potential of the provirus, it is often possible to have both the gene and gene product in hand.

We thank Drs S. Hino, J. Stephenson, S. Aaronson, M. Gardner, W. Parks, W. P. Rowe and J. Hartley for certain viruses used in this study and for discussions. We thank Dr F. Dixon for mouse sera, and acknowledge the technical assistance of Ms J. Hampton and A. Chen. This research was supported by a grant from the US NCI.

Galactic distribution of X-ray burst sources

By applying the following working definition for X-ray bursts¹—rise times of less than a few seconds, durations of seconds to minutes, and recurrence in some 'regular' pattern—18 burst sources have been observed to date (refs 2–16) of which one (observed by SAS-3) has not yet been reported. Their positions are shown in Fig. 1. If single 'burst' events which meet the criteria of rise time and duration but not recurrence are accepted, seven burst sources can be added^{16–19}, of which two (observed by OSO-8) have not yet been reported. These seven are also indicated in Fig. 1.

Many other 'burst' events have been reported in the literature^{20–23} but are omitted here, since they meet neither the criteria of rise time nor recurrence. It is very likely, however, that some of the many events observed by the Los Alamos group^{20–22} were X-ray bursts of the kind discussed here. Evans (private communication) believes that perhaps five or six burst sources have been found by them. Since sufficient knowledge about the rise times and the recurrence pattern of these events is lacking, they are not included in Fig. 1.

The burst sources are spread along the galactic equator and cluster near low galactic longitudes ($|l| < 40^\circ$). Lewin¹⁸ concluded, on the basis of the positions for 15 X-ray burst sources, that their distribution is different from that of the observed globular clusters²⁴. On the basis of an even smaller sample of some of the SAS-3 results, Lewin¹ also concluded that the

distribution of burst sources is unlike that of the previously known (catalogued) galactic X-ray sources²⁵, but pointed out that the burst sources could well be a subclass of the galactic X-ray sources.

The SAS-3 X-ray observatory and the Goddard X-ray Spectroscopy Experiment on OSO-8 have discovered 21 of the 25 burst sources shown in Fig. 1. Here we examine the distribution of burst sources and evaluate (with improved statistics) the effect of uneven sky exposure on the observed distribution, using data from these two observatories. In our analysis we include sources from which single 'burst' events have been observed; none of our conclusions would change if we ignored them.

From the SAS-3 observatory, we present only data from the rotating modulation collimator detectors²⁶ (RMC), which have $\sim 12^\circ \times 12^\circ$ (FWHM) fields of view. The RMC systems view the sky in the direction of the spin axis ($+z$ axis). Their view direction therefore does not change rapidly, and the sky exposure can be easily calculated. We have thus ignored several sources from which bursts were detected in the SAS-3 y -axis detector systems only^{7,8,15}.

The OSO-8 burst observations were made with three independent detectors viewing the directions of the $+z$ axis (spin axis) and that of the $-z$ axis. The detector that views the sky in the $+z$ direction has a circular field of view of $\sim 5^\circ$ FWHM. Two detectors view the sky in the direction of the $-z$ axis; one has a circular field of view of $\sim 3^\circ$ FWHM (centred on the $-z$ axis) and one has a circular field of view of $\sim 5^\circ$ FWHM (this one is offset from the $-z$ axis by 5°). These OSO-8 detectors have been described in more detail by Serlemitsos *et al.*²⁷. For the present purpose, the two $-z$ axis detectors can be considered as one detector system with a circular field of view of radius $\sim 10^\circ$ centred on the $-z$ axis. This is certainly valid for observations of bursts that last longer than ~ 20 s, since the spin period of OSO-8 is ~ 10 s. For shorter bursts, the equivalent field of view decreases by a factor of up to 2.

The sensitivity of each detector for detecting bursts depends on the detector area, the background level, the field of view and the exposure time. For the SAS-3 RMC and the OSO-8 $5^\circ - z$ axis detectors, the sensitivity is also adversely affected by modulations of strong sources due to rotation of the satellites. We do not attempt here to draw any conclusions from a comparison of the number of burst sources seen by the three different detectors.

The calculated sky exposure (in days) and the number of burst sources observed are shown in Tables 1 and 2. The results were calculated using 'clean' data only. As a result of Earth occultation, the actual values for the sky exposure were $\sim 30\%$ less (mean value) than those shown in the tables. The SAS-3 results are primarily from 'quick look' data ($\sim 50\%$ of the total data collected) during the first 19 months of observations (up to January, 1977). The OSO-8 results are from the first 16 months of observations (up to October 1976); for the last 4

Fig. 1 Sky map (galactic coordinates) of 18 X-ray burst sources which meet the three burst criteria (see text). Seven additional sources are shown for which the recurrence criterion of the bursts has not (yet?) been met. They are indicated with dashed lines (four sources) or with vertical bars (three sources). Open error boxes have areas ≥ 3 deg². The dashed line near the galactic anticentre represents an error box of $\sim 120^\circ \times 2^\circ$. The figure contains only burst sources discovered before 6 January, 1977. For more detailed information see ref. 18.

Table 1 Galactic latitude distribution of observed X-ray burst sources

months, only 'quick look' data ($\sim 10\%$ of the total) are available. For OSO-8, the sky exposure at any absolute value of the galactic latitude is obviously the same for the $+z$ and the $-z$ detectors. We have therefore combined the data of the OSO-8 $+z$ and $-z$ detectors in Table 1 (but not in Table 2).

The numbers of burst sources listed in Table 1 observed by SAS-3 (RMC) and OSO-8 at low galactic latitudes ($|b''| < 20^\circ$) are nine and thirteen respectively. (These numbers are lower limits because of possible source confusion. We estimate that perhaps two or three more sources were detected in the region of high burst source density within $\sim 10^\circ$ of the galactic centre.) Three of the thirteen sources observed by OSO-8 were also observed by SAS-3 (RMC). Therefore, nineteen different burst sources are observed in the region $|b''| < 20^\circ$. One burst source was observed at galactic latitude $|b''| > 20^\circ$; this source, observed by SAS-3, has not been reported previously. The sky exposure for SAS-3 in the region $|b''| > 20^\circ$ was about twice that in the region $|b''| < 20^\circ$; for OSO-8 the exposure at low galactic latitude was about twice that at high galactic latitude.

The combined results of SAS-3 and OSO-8 illustrate unambiguously that the galactic latitude distribution of X-ray burst sources is very different from that of the known globular clusters²⁴ (see last column Table 1).

The galactic longitude distribution of X-ray sources for which $|b''| < 20^\circ$ is shown in Table 2. Again, the numbers of observed sources given for the region $|l''| < 60^\circ$ are lower limits (see above). In regions of low galactic longitude ($|l''| < 60^\circ$) the OSO-8 $-z$ and $+z$ detectors observed nine and six

We conclude from the combined OSO-8 and SAS-3 results of Table 2 that the galactic longitude distribution of X-ray burst sources is different from that of the low galactic latitude X-ray sources listed in the 3U catalogue²⁵ (see Table 2). It is quite possible, however, that the burst sources are a subclass of the low galactic latitude X-ray sources. Five of the twenty-five burst sources shown in Fig. 1 and possibly many more of them (refs 1, 9, 16, 18, 19) are associated with sources of steady X-ray emission.

It is interesting to note that the galactic longitude distribution for known globular clusters (in the region $|b''| < 20^\circ$) is similar to that of burst sources (see last column, Table 2). It has been proposed (see discussion in ref. 1) that perhaps the majority of burst sources are located only in those globular clusters near the galactic plane, but as pointed out earlier¹ this is very unlikely. There are at present sixteen X-ray burst sources whose positional uncertainties exclude known globular clusters; two burst sources are located in globular clusters (one in NGC6624 and the rapid burster), and seven additional burst sources could be located in globular clusters (it is very unlikely that all seven are). Therefore, of the ~ 65 known globular clusters (ref. 24) in the region $|b''| < 15^\circ$, two or at most eight are known to produce bursts. Thus, for every known globular cluster that is known to produce bursts there are ~ 8 – 30 that are not known to produce bursts. If the 16 burst sources whose positions exclude known globular clusters were located in obscured globular clusters, and if the occurrence of a burst source is as probable in obscured clusters as in the known ones, then there would have to be an additional 130–480 obscured globular clusters within 15° of the galactic plane. Their distribution would be very different from the spherical distribution of the known globular clusters, and they would constitute, in effect, a distinct disk population of globular clusters. To avoid this, one might assume that an intense concentration of matter in the immediate vicinity of many globular clusters is responsible for the obscuration of these clusters and that the presence of this obscuring matter somehow increases the probability of the occurrence of burst sources. We believe it is more likely that the majority of X-ray burst sources are not

Table 2 Galactic longitude distribution of observed X-ray burst sources for $|b''| < 20^\circ$

†The source at $l'' \sim 250^\circ$ (see Fig. 1) is located at $|b''| > 20^\circ$ and is therefore not included.

burst sources, respectively. Four of these sources were observed by both detectors. Therefore, eleven different burst sources were detected by OSO-8, of which three were also observed by SAS-3. Thus, a total of sixteen different burst sources were observed by the two observatories in the region of low galactic longitude ($|l''| < 60^\circ$). One burst source was observed by SAS-3 near galactic longitude $l'' \sim 114^\circ$ (refs 17, 18) and one was observed by OSO-8 (unpublished) near $l'' \sim 79^\circ$. OSO-8 observed one burst source (unpublished) at high galactic longitude $|l''| = 120^\circ$ – 180° . (One other burst source was observed at high galactic longitude with one of the SAS-3 y -axis detector systems (dashed line in Fig. 1, refs 1, 18). The Los Alamos group may have detected three additional burst sources (refs 20–22) in this region. However, as mentioned earlier, the 'burst' character of these events is not yet established. The source at $l'' \sim 250^\circ$ (see Fig. 1) is located at $|b''| > 20^\circ$ and is therefore not included in Table 2.)

located in globular clusters of the kind that we know. This conclusion is supported by the direct observational evidence of Liller, who systematically searched for globular clusters in the vicinity of six burst sources and found only one²⁸. In five cases no globular clusters were apparent on his infrared plates (ref. 29). Liller believes that, in the case of MXB1728-34 for example, he would have detected a globular cluster out to a distance of ~ 19 kpc (ref. 29).

It has also been suggested (discussion in ref. 1; ref. 30 and T. Gold, unpublished) that the bursts are perhaps produced by remnants of disrupted globular clusters, specifically super-massive black holes. Such objects could perhaps accrete a sufficient amount of gas in the galactic plane (but not away from the plane) to produce bursts. Again, this would imply the existence of a new class of unknown objects and is at present merely an *ad hoc* method of relating the burst sources to globular clusters.

First mass spectrometric measurements of positive ions in the stratosphere

ROCKET and balloon-borne electrostatic probe measurements have shown that positive and negative ions are present in the stratosphere reaching number densities between 100 and 10,000 cm^{-3} (refs 1-5). The observed densities indicate that galactic cosmic radiation is the major ionisation source and mutual recombination is the dominant ion loss process. No experimental information exists, however, on the nature of stratospheric ions. Here we communicate the first mass spectrometric measurements of positive ions in the stratosphere.

Three experiments were carried out at high latitudes (experiment F 33, 31 May 1972, 06.53 UT, latitude 69°N; experiment F 42, 10 June 1975, 13.19 UT, latitude 69°N; experiment S 18-1, 21 February 1976, 19.42 UT, latitude 68°N) using rocket-borne cryogenically pumped quadrupole mass filters. Mass spectra of positive ions at stratospheric heights were obtained between 24 km and 60 km during the descent portions of the rocket flights.

The mass numbers of the most abundant ions detected are listed in Table 1 along with tentative identifications. The uncertainty of ± 2 in atomic mass numbers is due to a relatively low mass resolution used in favour of high sensitivity. Above about 40 km the masses 19 ± 2 , 37 ± 2 , 55 ± 2 and 73 ± 2 are most abundant which are identified as proton hydrates (PH)

Table 1 Observed mass numbers and tentative identifications of ions

Mass (AMU)	Tentative identification of ions
19 ± 2	H_3O^+
29 ± 2	$\text{H}^+\text{CH}_2\text{O}$
37 ± 2	$\text{H}^+(\text{H}_2\text{O})_2$
42 ± 2	$\text{C}_2\text{H}_2\text{O}^+$
55 ± 2	$\text{H}^+(\text{H}_2\text{O})_3$
60 ± 2	$\text{H}^+(\text{CH}_2\text{O})_2$; $\text{C}_2\text{H}_2\text{O}^+\text{H}_2\text{O}$
80 ± 2	$\text{H}^+(\text{CH}_2\text{O})_2\text{H}_2\text{O}$; $\text{C}_2\text{H}_2\text{O}^+(\text{H}_2\text{O})_2$

$\text{H}^+(\text{H}_2\text{O})_n$ with n ranging from 1 to 4. It should be noted that PH were also found above 55 km in the mesosphere by these experiments. Here the mass filters were additionally operated in a second mode using higher mass resolution. Therefore, the identification of the above masses as PH seems to be quite safe. Below about 40 km the PH rapidly disappear and ions having masses 29 ± 2 , 42 ± 2 , 60 ± 2 and 80 ± 2 become most abundant. The change in the ion population occurs within only a few kilometers as demonstrated by Fig. 1 showing the fractional abundance of non-proton hydrates (NPH). The NPH probably result from PH reacting with one or more stratospheric trace gases by switching or proton transfer reactions. The unknown reaction partner should have either a higher permanent dipole moment or a higher proton affinity than H_2O or both and its number density should steeply decrease with height around 40 km. An inspection of molecules which satisfy condition one and which after adding a proton fall into the mass interval 29 ± 2 AMU corresponding to the observed ion of smallest mass yields the following candidates: CH_2O , HCN , CH_3N and CH_3NH_2 . Certainly, these species do not represent a complete list but were chosen also on the base of aeronomical arguments. Although, however, none of these species has been measured in the stratosphere so far, at least CH_2O is expected to be present in substantial concentrations resulting from the oxidation of methane⁶. The proton affinity of CH_2O ($165 \pm \text{kcal mol}^{-1}$) only slightly exceeds that of H_2O ($164 \pm \text{kcal mol}^{-1}$) as also proven by the qualitative observation of H_3O^+ proton transfer with CH_2O (ref. 7). The higher masses observed in our experiments also seem to fit into the concept of a stratospheric formaldehyde ion chemistry. Mass 42 ± 2 might be identified as $\text{C}_2\text{H}_2\text{O}^+$ which has already been observed⁸ in the laboratory as a product of $\text{H}^+\text{CH}_2\text{O}$ reacting with CH_2O . The masses 60 ± 2 and 80 ± 2 might be identified as the cluster ions $\text{H}^+(\text{CH}_2\text{O})_2$ or $\text{C}_2\text{H}_2\text{O}^+\text{H}_2\text{O}$ and $\text{H}^+(\text{CH}_2\text{O})_2\text{H}_2\text{O}$ or $\text{C}_2\text{H}_2\text{O}^+(\text{H}_2\text{O})_2$ respectively. The number density of the reaction partner X of PH can be estimated from the measured density ratio of NPH and PH. Assuming a chemical

Fig. 1 Fractional abundance of non-proton hydrates. ●, F33; ■, F42; ▲, S18.

equilibrium, the continuity equation

$$[\text{PH}^+] K [\text{X}] = [\text{NPH}^+] \alpha [\text{N}^-]$$

relates $[\text{X}]$ to the measured density ratio $[\text{NPH}^+]/[\text{PH}^+]$ the reaction coefficient K , the mutual recombination coefficient α and the negative ion density $[\text{N}^-]$. Taking a typical $\alpha = 5 \times 10^{-8} \text{ cm}^3 \text{ s}^{-1}$ based upon laboratory measurements⁹, a lower limit for $K = 10^{-10} \text{ cm}^3 \text{ s}^{-1}$ and a typical measured $[\text{N}^+]$ ² (which due to the absence of free electrons equals $[\text{N}^-]$) the $[\text{X}]$ profiles shown in Fig. 2 are obtained. When compared with the relative profile of the total gas density $[\text{M}]$ the $[\text{X}]$ profile steeply decreases above about 40 km as does a model profile of CH_2O (ref. 6). Even the absolute $[\text{X}]$ values, although uncertain mainly due to the assumed K and $[\text{N}^-]$ values, seem to be of the right order of magnitude. This similarity may provide further support for the identification of NPH as products of CH_2O reactions. The following simplified reaction scheme is proposed

Fig. 2 Number densities of the unknown reaction partner X as derived from the data. The total gas density M (ref. 12) and a theoretical CH_2O profile⁶ are shown for comparison. ●, F33; ■, F42; ▲, S18.

(Fig. 3). The primary ions N_2^+ , O_2^+ , N^+ and O^+ which are formed by galactic cosmic radiation rapidly convert to proton hydrates. While the ion lifetime against mutual recombination is about 2,000 s or greater the PH-formation and PH-growth to an equilibrium size distribution proceeds within less than 0.01 s at 40 km. As soon as the number density of a potential reaction partner X for the PH exceeds a critical value of about $5 \times 10^6 \text{ cm}^{-3}$ (value for which $[\text{NPH}] = [\text{PH}]$) the PH-conversion becomes effective. According to measured equilibrium constants for PH (ref. 10) the most abundant PH at 40 km should be $\text{H}^+(\text{H}_2\text{O})_4$ and $\text{H}^+(\text{H}_2\text{O})_5$.

As formaldehyde not only has a higher proton affinity but also has a higher permanent dipole moment¹¹ (2.27 debye) than water (1.84 debye) it should replace H_2O when reacting with $\text{H}^+(\text{H}_2\text{O})_n$. As the difference of the CH_2O - and H_2O bond energies is probably smaller than the bond energy of the $(n-1)$ th H_2O no additional H_2O will be 'boiled off'. The product ion $\text{H}^+(\text{H}_2\text{O})_{n-1}\text{CH}_2\text{O}$ may undergo additional exchange reactions with CH_2O which may finally lead to $\text{H}^+(\text{CH}_2\text{O})_n$. Also further association of CH_2O may occur resulting in complexes $\text{H}^+(\text{CH}_2\text{O})_k$ of higher order of association ($k > n$) than the original PH. It may also be considered that the excited complex $[\text{H}^+(\text{H}_2\text{O})_n\text{CH}_2\text{O}]^*$ formed by association of CH_2O to $\text{H}^+(\text{H}_2\text{O})_n$ does not stabilise by ejection of an H_2O molecule but by ejection of molecule fragments. Cluster ions containing $\text{C}_2\text{H}_2\text{O}^+$ as a central ion might have been formed by such

Fig. 3 Simplified reaction scheme for stratospheric positive ions at heights above 24 km. Reaction partners are indicated beside or above the arrows. M denotes an N_2 or O_2 molecule and Y denotes a molecule having a higher permanent dipole moment or proton affinity or both than CH_2O . GCR denotes galactic cosmic radiation.

processes. This was suspected previously from laboratory experiments⁸. Drift tube mass spectrometer studies carried out in our laboratory¹³ indicate that proton hydrates $\text{H}^+(\text{H}_2\text{O})_n$ with n ranging from 1 to 4 rapidly react with formaldehyde. It was also found that the product ions of the $\text{H}^+(\text{H}_2\text{O})_n + \text{CH}_2\text{O}$ process undergo a fast reaction with NH_3 resulting in $\text{NH}_4^+(\text{NH}_3)_n$ ions. Therefore an upper limit of atmospheric NH_3 at 24 km may be estimated from our stratospheric ion data. In contrast to the above estimate of CH_2O , three-body recombination has also to be considered at 24 km yielding an increased total recombination coefficient and thus an increased critical number density for a potential reaction partner of formaldehyde related ions. Taking a three-body recombination coefficient of $2.10^{-25} \text{ cm}^6 \text{ s}^{-1}$ (ref. 14) one obtains an effective recombination coefficient of $2.1 \cdot 10^{-7} \text{ cm}^3 \text{ s}^{-1}$ at 24 km. As no NH_3 related ions were found at 24 km the relative abundance of $\text{NH}_4^+(\text{NH}_3)_n$ ions was less than 0.07 corresponding to $[\text{NH}_3] \leq 7 \cdot 10^4 \text{ cm}^{-3}$.

Finally, two points should be stressed. First, that the observed ions could possibly represent fragments of ambient ions formed by electric field or shock wave-induced collisional breakup during sampling. As fragmentation causes successive stripping-off of neutral molecules (presumably CH_2O and H_2O) attached to the central ion, the nature of the central ion remains unchanged and so do the general conclusions drawn here. Second, one must consider the powerful diagnostic possibilities of stratospheric ion composition measurements for the detection of stratospheric neutral trace gases and even for a determination of their concentrations. Future *in situ*-measurements using higher mass resolution as well as laboratory studies of the relevant ion chemical processes are needed before these possibilities can be exploited.

Methyl chloroform in the troposphere as an indicator of OH radical abundance

METHYL chloroform (111 trichloro ethane) was introduced into general use in 1955-60 in response to the need for a general solvent which was less toxic than those then in use. Its ubiquitous presence in the northern and southern hemispheres, first reported in 1974 (ref. 1), has since been confirmed^{2,3}. The only significant sources of methyl chloroform are industrial releases from its use as a cleaning agent and solvent. A principal sink for its removal from the atmosphere seems to be the reaction with OH radicals. The rate of its release to the atmosphere is known with some accuracy, and consequently the measurements of its growth in the atmosphere could provide valuable information on the strength of the OH reaction sink, not only for methyl chloroform but also for other important atmospheric gases which undergo similar reactions. This communication reports measurements of the abundance of methyl chloroform made during 5 yr in the northern and southern tropospheres.

Methyl chloroform was analysed directly from 5-ml air samples using a gas chromatograph equipped with an electron capture detector. The method was that described for other halocarbons, including the fluorocarbons and carbon tetrachloride⁴. Figure 1 shows the concentration observed during the past 5 yr at measuring sites in rural

Fig. 1 Observed concentrations: parts per 10^{12} by volume of CH_3CCl_3 in the northern hemisphere (British Isles) and southern hemisphere (South Africa and Antarctica) during 1972-77. Cumulative releases (○) are in megatonnes.

regions of the British Isles, in the southern hemisphere in Cape Province South Africa and aboard the RV Shackleton. Northern hemisphere measurements were all made, except in 1972, during periods of unpolluted Atlantic air.

The observations in the southern hemisphere have been followed from just about the noise level in 1971, at an abundance of 1.2×10^{-11} , to the present level of 5×10^{-11} . The low initial finding suggests that there is no significant natural source of this compound. The absolute accuracy of the analytical method is not likely to be worse than 30% which is in general agreement with the experience of other analysts^{2,4}. Figure 1 also shows the annual releases of methyl chloroform to the atmosphere from industrial sources (personal communication from W. B. Neeley and J. Plonka). When applied to the observations here reported, using a simple two box model of the atmosphere, these data suggest an atmospheric residence time of between 5 and 10 yr. H. B. Singh (personal communication) reports observations also pointing to a longer residence time for methyl chloroform. Previous estimates of the residence time have varied from 1 to 2 yr (refs 3 and 5). It is unlikely that the measured rate of reaction of OH radicals with methyl chloroform⁶ is seriously in error, and the most likely source of the anomaly is in the time averaged value assumed for the OH concentration. The yearly average concentration is usually taken to be in the range $3-5 \times 10^9$ radicals per ml. This is a mean of several estimates⁷⁻⁹. One outstanding exception, however, is the estimate by Warneck¹⁰ of 7×10^5 per ml, for the yearly average. This lower value is more consistent with the observations reported here. The discrepancy in OH concentration is considerable and if it propagates to the reaction of the other atmospheric gases such as methane, CO and other hydrocarbons, could influence the interpretation of the chemistry of both the troposphere and the stratosphere. The comparatively uncomplicated industrial source and natural OH sink of this gas suggests that it may serve as a useful indication of the distribution of OH radicals.

Crutzen⁸ has discussed the consequences of the presence of this compound on the ozone layer. If current theories of ozone depletion by chlorine-containing species are confirmed by atmospheric measurements and if methyl chloroform is produced in ever increasing quantities for several decades, I agree with Crutzen that the atmospheric burden would give cause for concern.

I thank Shell Research Ltd, the NERC and the Manufacturing Chemists' Association for support.

Inhomogeneities in the water properties of fogs and clouds

ALTHOUGH there is good evidence that entrainment of undersaturated environmental air exercises a profound influence upon the development of the droplet spectra in clouds, the classical description of the mixing process¹ has

Table 1 Values of droplet concentrations N , water content C , mean radius r , and dispersion S measured within hill fog (mean spacing of consecutive spectra about 3 m)

failed to yield quantitative predictions of spectral evolution which are consistent with observation. In the classical model the mixing process is homogeneous, that is, all droplets at a given level within the cloud are, at any time, exposed to identical conditions of supersaturation or undersaturation. Recent laboratory experiments¹, however, have indicated that the mixing process in clouds may be highly inhomogeneous, with some droplets completely evaporated, or substantially reduced in size, and others negligibly influenced. This work² led to the formulation of a primitive model of inhomogeneous mixing in which it was predicted that sizeable fluctuations in the water properties of natural clouds should exist, on scales commensurate with those of the mixing process. In particular, it was proposed that there may exist closely adjacent regions in which the liquid water content was very different but the spectral shape essentially unchanged. Some recent field evidence supports this idea³ but few observational data are currently available. We describe here some preliminary results indicative of the highly inhomogeneous nature of the water properties of some clouds, on certain spatial scales.

An electrostatic disdrometer⁴ has been used to measure the size distribution of droplets within cloud and fog at

the disdrometer, of droplet concentration, N , water content, C , mean drop radius r , and spectral dispersion, S (defined as the ratio of the standard deviation to the mean size), for consecutive spectra spaced about 3 m apart in orographic hill fog. Measurements were made ~150 m above the cloud base. Since collection efficiency calibrations of the device are not complete the values of each of these four parameters, although acceptable relative to each other, are not absolute, and thus no units are attached to them. It is seen that considerable variations exist, on a scale of less than 10 m, in the water content of the fog. C varies by up to a factor of about 2.5, while the mean radius r is fairly constant. The dispersion of the spectrum undergoes significant variations, but closely spaced regions of similar values of S but widely different water content are also observed.

Table 2 presents a typical set of spectral parameter values measured several hundred metres above the base of a precipitating cloud, with consecutive spectra spaced about 50 m apart. Here, the fluctuations are much smaller than for the case presented in Table 1 and the measured dispersion is substantially higher. Although the liquid water content is appreciably higher than for the hill fog the mean radius

the UMIST field-research station on the summit of Great Dun Fell (870 m above sea level) in Cumbria. Orographic effects are generally of great importance in the formation of these clouds. Droplets are sampled and sized continuously at a rate of several hundred per second with the disdrometer, which can be mounted either on a platform close to the ground or on a 30 m mast. The level of spatial resolution of the water properties of the clouds is dependent on the horizontal wind speed, which was measured. In light winds statistically meaningful spectra can be obtained at intervals down to several metres; and in winds of around 25 m s^{-1} , characteristic of this site, the minimum spatial scale that can be studied is some tens of metres.

Table 1 presents a typical set of values, obtained with

Fig. 1 Characteristic droplet spectra measured in (a) orographic hill fog, (b) precipitating cloud. N is the droplet count. The channels are $0.9 \mu\text{m}$ wide, and channel 2 corresponds to a radius of $5.2 \mu\text{m}$.

is significantly lower (by about $0.3 \mu\text{m}$). This could be a consequence of preferential capture by raindrops of the larger droplets within the condensate spectrum.

Figure 1 presents characteristic uncorrected spectra obtained for the two situations covered by Tables 1 and 2. In both cases the principal contribution to the water content of the spectrum is provided by droplets in a narrow central size band; the contribution from the largest droplets in the spectrum is very small. Statistical analysis shows that fluctuations in water content observed cannot be a consequence of randomness in rate of arrival of droplets; this conclusion was confirmed in laboratory tests using a cloud tunnel.

Preliminary results obtained so far indicate that, on certain spatial scales at least, very considerable fluctuations exist in the water properties of clouds and fogs, and we hope that future work will provide more quantitative information on the nature of these inhomogeneities in a variety of meteorological conditions.

Fine structure in caustic junctions

EVERYONE has seen the changing patterns of bright caustic lines traced on the sea bed or on the bottom of a swimming pool^{1,2}. The caustics are formed when sunlight is focused after refraction by smooth waves on the water surface; similar caustics can result from reflection. Here we draw attention to one feature of these patterns: the frequent occurrence of junctions at which three caustics appear to meet (Fig. 1).

It might seem that this is not worthy of comment—after all, the stability of triple junctions under perturbation makes them widespread in many natural systems of lines and surfaces^{3,4} such as mud cracks, foams, and the markings on giraffes. But triple junctions in caustic patterns would be surprising. The reason is that, except in special circumstances, the forms of caustics are restricted to be 'elementary catastrophes'⁵⁻⁶ and in two dimensions (i.e. two 'control variables') these are smooth curves ('fold' catas-

Fig. 1 Caustics formed by a wavy water surface (after Minnaert¹).

trophenes) which may have cusp points: triple junctions occur nowhere in the list of elementary catastrophes. The qualification 'except in special circumstances' implies the assumption of genericity that underlies catastrophe theory. It means in this case the absence of high symmetry in the wavefront whose normals envelop the caustic and is certainly satisfied for the random water waves considered here.

These considerations suggest that the triple junctions are illusory. In fact they are the appearance under low resolution of a caustic structure with fine detail on several levels. The following argument shows that this structure involves the meeting of six lines rather than three. Below each

Fig. 2 Line pairs where caustic surfaces from ridges intersect the sea bed.

Fig. 3 Glass 'lollipop' on whose surface three grooves meet.

'ridge' on the water surface is a caustic surface with two sheets that meet along a cusped edge (Fig. 2); if the sea bed intersects this surface it will generally do so in two almost-parallel lines (these are easily seen in sunlight in, say, 2 m depth of water on which the waves are long-crested). The ridges meet in threes on the water surface, and the associated meetings of three line pairs on the sea bed are the 'triple junctions' under discussion.

Fig. 4 Typical fine structure in caustic junction, formed by refraction of white light from a small distant source through the 'lollipop' of Fig. 3 and photographed with the aid of a microscope.

To study the details of such a junction 'in vivo' would be difficult in view of its rapid motion and the blurring caused by the 0.5° divergence of rays from different parts of the Sun. Therefore conditions near the junction of three ridges were simulated 'in vitro' on the surface of the disk of a glass 'lollipop' (Fig. 3) formed in the molten state. The diameter of the disk was 40 mm. White light from an illuminated pinhole was viewed through a microscope after being refracted by the disk. (It was easier to produce grooves on

Fig. 5 The photographs show a typical through-focus sequence of caustic patterns with the lollipop tilted through a large angle, approaching the lollipop from *a* to *g*; diffraction blurs the details. The line drawings show an unfolding of the caustic devised using catastrophe theory. An elliptic umbilic occurs at *b*; piercing (ref. 4, p. 86) occurs between *b* and *c*; swallowtails occur between *e* and *f* and between *f* and *g*; beak-to-beak singularities occur between *c* and *d* and between *e* and *f*. Beyond *g* (i.e. close to the lollipop) a further beak-to-beak singularity occurs, separating the two bottom lines and leaving three cusps which recede from the field of view.

the glass surface rather than ridges, so that the caustics were virtual rather than real.) In this way the three line pairs were easily resolved and typical patterns do indeed show the smooth curves and cusps anticipated on the basis of catastrophe theory (see Fig. 4). Note the inner cusped

'triangle', for this provides the key to the understanding of the higher-dimensional caustic structures now to be discussed.

Altering the focus of the microscope introduces an additional control variable which enables the three-dimensional

Fig. 6 Singular section of a higher catastrophe.

caustic surface to be explored in two-dimensional sections. In nature this new variable could represent time. A 'through-focus' sequence of patterns is shown on Fig. 5a-g. The complicated changes in caustic structure must be governed by catastrophe theory with three control variables. In our experiments the finest details of some of these changes were obscured by characteristic diffraction effects; the intensity and linear scale of the diffraction effects increase, for fixed wavelength, with the order of the singularity. According to catastrophe theory, cusp points may appear and disappear in pairs, either at beak-to-beak or lip singularities^{4,5} (where the plane of focus touches a cusped edge of the caustic surface) or at swallowtail catastrophes (singular points of the caustic surface). Guided by these principles it was possible to devise a series of catastrophes (the line drawings on Fig. 5) to account for the transformations on the photographs. The line drawings show the patterns that would be formed in the limit of geometrical optics where the wavelength approaches zero. There are further singular points of caustic surfaces, associated with elliptic and hyperbolic umbilic catastrophes, but since these catastrophes are symmetric in their unfoldings they do not result in changes in the topology of the two-dimensional patterns; an elliptic umbilic occurs on Fig. 5b as the cusped 'triangle' shrinks to a point and expands again. All this behaviour is typical (generic): no special care is required in orienting the lollipops or in manufacturing them (other than making them smooth). Qualitatively identical phenomena were also observed in reflection.

The tilting of a lollipop provides two more control variables, θ_1 and θ_2 , say. By changing θ_1 it is possible to find a through-focus sequence where the cusped triangle shrinks to a point just as it reaches one of the caustic lines; this is a parabolic umbilic catastrophe point P on the three-dimensional caustic hypersurface in the four-dimensional control space C. The sequence on Fig. 5 constitutes a three-dimensional section S of C, and the fact that P lies close to S explains the small scale of detail in the patterns. In Thom's terminology⁴ the parabolic umbilic is the 'organising centre' for caustics near P and its unfolding justifies the sequence of patterns in the line drawings of Fig. 5. It is also possible to make two swallowtails coincide; this is a butterfly catastrophe. Finally, by also changing θ_2 this butterfly and parabolic umbilic can be made to coincide at one stage in the through-focus sequence; the two-dimensional pattern (Fig. 6) is then a singular section of

the higher-order catastrophe, presumably involving five control variables, which organises all the triple junction caustic patterns discussed here.

We draw two conclusions from this study. First, nature's line patterns are not all of the same sort; the triple junctions generic in mud cracks cannot occur with caustics. Second, the geometrical optics of cylindrically symmetric artefacts such as telescopes, where departures from the ideal point focus are treated as 'aberrations', is very different from the geometrical optics of nature, where the generic forms of caustic surfaces are governed by the mathematics of catastrophe theory.

We thank Mr Tony Osman for making the 'lollipops'.

Polarised infrared cathodoluminescence from platelet defects in natural diamonds

WE report here that the large platelet defects occasionally found in natural diamonds emit polarised cathodoluminescence in the near infrared. Lattice defects in natural diamonds attract as much scientific enquiry today as at any time since the anomalous 'spike' diffuse X-ray reflections from single-crystal diamonds were discovered¹. That platelet-type defects segregated on {100} planes of the diamond matrix could well account for the 'spike' X-ray reflection observations^{1,2} was shown by Frank³. Transmission microscopy⁴ revealed just such platelets, with diameters generally in the range 10 to 100 nm, profusely present within the most common form of diamond (Type Ia). Mendelssohn⁵ described a specimen containing platelets on {100} that were more than two orders of magnitude greater in diameter than those that had become well known through transmission electron microscopy. The large platelets emitted a green-yellow cathodoluminescence which made them conspicuous when they lay not deeper below the specimen surface than the penetration range of the bombarding electron beam ($\sim 10 \mu\text{m}$). Work in our laboratory has shown that platelets on {100} span the gamut of sizes from the largest observed by Mendelssohn down to the more familiar sub-micrometre objects seen electron-microscopically. This knowledge has been acquired by combining X-ray topography (using both normal Bragg reflections and the anomalous 'spike' reflections), cathodoluminescence topography, ultraviolet absorption topography and transmission electron microscopy at 100 kV and 1 MeV (refs 6,7). Platelets exceeding 5-10 μm in maximum dimension are rare compared with those of sub-micrometre size; but our experience affords us a good chance of identifying solely by X-ray topography regions within diamonds where there reside platelets having extreme dimensions exceeding 1-2 μm (and such platelets we dub 'giant').

We conclude⁶ that the principal visible emission from individual platelets is the 'H3' system^{8,9}; although in our experiments (so far done only at or slightly above room temperature) we have not yet succeeded in spectrographically recording the 2.46 eV zero-phonon line in the weak spectra of single platelets. The polarisation of the visible cathodo-

luminescence from platelets⁶ is notable: the measured ratio of intensity emitted with **E** vector in the platelet plane to that with **E** vector normal to the platelet being about 10.

There is much uncertainty regarding composition and structure of the platelets¹⁰⁻¹². Apart from expressing dissent with the view of Evans¹³ and Woods⁷ that the platelets are composed of interstitial carbon atoms, we will not debate this topic since our concern is to present new findings on the optical properties of platelets. The discovery that cathodoluminescence from giant platelets can be seen in the near infrared using an image converter has been briefly reported⁶. This observation has been followed up by photographic recording with Kodak High Speed Infrared film. It has now been discovered that the infrared emission from platelets is polarised with **E** vector in the platelet plane, but with a considerably higher polarisation ratio than in the case of their visible emissions.

The cathodoluminescence topographs in Fig. 1 (taken by means similar to those previously described¹⁴) show part of the specimen C19 studied by Mendelsohn. Here platelets range up to 40 μm in extreme dimensions. Differing brightnesses of platelets which lie in the cube plane nearly parallel to the specimen surface result from their differences in depth below the surface; these images are unaffected by rotation of the Polaroid filter. (In this specimen fan-shapes and kite-shapes predominate among the largest platelets; in other specimens elongated shapes aligned randomly along one or other of the two $\langle 110 \rangle$ axes in the platelet plane are more common.) The appreciable width of edge-on platelet images arises from shortcomings of the optical system which was not designed for infrared use. Contrast between platelets and matrix is far superior to that in the visible region where platelet emission has to compete with the low-energy tail of the cathodoluminescence continuum known as Band A (refs 9, 15). To facilitate comparison of features in Fig. 1, a Polaroid filter giving only partial extinction at infrared wavelengths was used. In experiments

undertaken to assess the degree of polarisation of the infrared emission we used Polaroid Type HR linear polariser which is highly effective at the longest wavelengths (about 900 nm) recordable by Kodak High Speed Infrared film. Despite a sixfold increase in electron beam current per unit area of specimen as well as reductions in optical magnification so as to maximise image brightness of the polarisation component attenuated by the Polaroid, we could determine only a lower limit, about 40, of the ratio of intensity of radiation with **E** vector parallel to the platelet plane to that with **E** vector normal to the platelet. Our results reinforce our earlier conclusion⁶ that we are observing the emission band peaking at 1.25 eV (990 nm) described by Wight *et al.*¹⁶ which correlates well with the infrared absorption at 170 meV (7.3 μm) generally accepted as a measure of total area of the common, sub-micrometre platelets in unit volume of specimen. The high degree of polarisation of platelet infrared emission constitutes a well-defined optical characteristic that any model for platelet structure (and for optical processes associated with platelets) must satisfactorily accommodate.

We thank Drs M. Mendelsohn and J. H. Milledge for the loan of the specimen and De Beers Industrial Diamond Division Ltd for financial support.

Fig. 1 Infrared cathodoluminescence from large platelets lying on cube planes in a natural diamond. The specimen surface is polished about 5° off (001) orientation: hence platelets close to the specimen surface and lying in (001) are seen nearly face-on. The direction $[110]$ points horizontally to the right. Platelets parallel to (100) are seen edge-on as bright lines running from top right to lower left, and those parallel to (010) as bright lines running from top left to lower right. Field width is 0.5 mm; the length of the arrows indicating **E** vector directions is 100 μm . Electron beam energy 20 kV, specimen current 1.1 $\mu\text{A mm}^{-2}$. Photographed on Kodak High Speed Infrared film through the visually opaque, infrared transmitting Kodak-Wratten filter 87C and through a Polaroid filter used for visible wavelengths. The lighter areas and strips seen trending roughly vertically on either side of the field are due to numerous smaller platelets not fully resolved individually which reside in crystal growth layers parallel to $(\bar{1}\bar{1}1)$ on the left and to $(11\bar{1})$ on the right. *a*, Polaroid rotated to transmit the **E** vector lying in the plane (100); *b*, lying in (010), as indicated by arrows.

Supported ^{242}Cm in the marine environment

BOWEN and Livingston¹ have reported the presence of ^{242}Cm (half-life 163 d) in two samples of sea water which had been kept in sealed containers for 12 yr since the time of collection. Because the ^{242}Cm originally present in the samples would have decayed completely after this period of storage, they suggested that the ^{242}Cm which they detect is supported by a long-lived precursor, $^{242\text{m}}\text{Am}$; this radionuclide would not itself be detectable in these samples because of its much longer half-life (152 yr). They invited other workers in radiochemistry to search for similar evidence for $^{242\text{m}}\text{Am}$ in the environment, and we have done so in some samples collected from the vicinity of the fuel-processing plant at Windscale where controlled discharges of transuranic nuclides to the marine environment are permitted under the provisions of the United Kingdom Radioactive Substances Act, 1960. The radiological implications of these discharges have been discussed by Hetherington *et al.*²

We obtained a sample on 15 December 1974 from the area of the processing plant and extracted the actinides from the sample matrix by strong acid digestion in oxidising conditions. After reduction with sulphur dioxide they were concentrated by coprecipitation, first on calcium oxalate and then on 5 mg of added neodymium carrier. Am, Cm and Nd were then separated from the Pu by anion exchange

in 9 M HCl and further purified by precipitation as fluoride in acid solution, followed by conversion to the hydroxide. Am and Cm were then separated from Nd by anion exchange in a 4 M NH_4SCN medium at 80 °C and electro-deposited on to a stainless steel disk from an $(\text{NH}_4)_2\text{SO}_4/\text{H}_2\text{SO}_4$ medium. ^{243}Am was used as a yield tracer.

The separated source of Am and Cm was first measured on 24 July 1975 by α -spectrometry and was then measured at intervals over a period of some 500 d to follow the decay of ^{242}Cm . The results are shown in Table 1.

Table 1 Decay of separated ^{242}Cm

Date	Decay period (d)	^{242}Cm (pCi)	^{241}Am (pCi)
24 July 1975	0	48.04 ± 1.79	43.1 ± 1.6
14 Jan. 1976	174	23.47 ± 0.36	—
17 May 1976	298	14.32 ± 0.27	—
12 Jan. 1977	538	5.07 ± 0.28	—

The $\pm$ figures denote σ error on counting only. Data are corrected for Am yield.

A regression on these data by the method of least squares produced a derived half-life value of 166.0 ± 2.1 (1 σ) d, which is very close to the accepted value for ^{242}Cm of 163 d; the coefficient of determination (r^2) was 1.00. If the half-life was taken as 163 d, however, and the assumption then made that the apparent longer half-life was due to a small, constant amount of ^{242}Cm , supported by a precursor with very long half-life, then the decay equation could be restated

$$(y-d) = K \exp(-0.693/163)t$$

where y is measured activity (total) of ^{242}Cm (pCi), d is supported ^{242}Cm (pCi), t is time of decay (d) and K is unsupported ^{242}Cm at time zero (pCi).

This equation can be arranged

$$y = d + K \exp(-0.693/163)t$$

A linear regression can again be performed with $\exp(-0.693/163)t$ as the x -value and the measured ^{242}Cm activity as the y -value. The value of d (the equilibrium value of supported ^{242}Cm) obtained in this way was 0.60 ± 0.32 (1 σ) pCi, compared with the ^{241}Am value of 43.1 ± 1.6 pCi. Thus the ^{242}Cm is $1.36 \pm 0.73\%$ of the ^{241}Am : this is significantly different from zero ($P=0.03$).

The analysis of other samples in the Windscale area has not included counting at intervals to measure decay of ^{242}Cm . But, following the procedure of Bowen and Livingston, Am and Cm were recently separated from some marine sediment samples collected in April 1973, some seven half-lives of ^{242}Cm after collection; in none of them did the total ^{242}Cm exceed 0.2% of the ^{241}Am , and the supported $^{242}\text{Cm}/^{241}\text{Am}$ in these samples can therefore be stated unequivocally to be $\geq 0.2\%$.

The results of the investigation indicate that little, if any, supported ^{242}Cm has been detected in this area but further work is in hand to check these preliminary data.

This work was supported in part by the Euratom Radiobiology Research Programme.

Are rare earth elements mobile during spilitisation?

FROM the study of rare earth elements (REE) in basalts, spilites and hydrothermally altered basalts in the ocean floor^{1–5}, ophiolites^{6,7}, geosynclines^{3,8} and low-grade to greenschist facies regions⁹ it has come to be accepted that the REE are immobile during rock alteration. This conclusion has led to the use of certain abundance ratios, particularly La/Sm and La/Yb, as indicators of parent magma type and genesis. Despite some suggestions^{2,10} that REE, such as La and Ce, may be mobile during sea-water/rock interaction, hydrothermal alteration or spilitisation of igneous rocks, the REE continue to be treated (e.g. refs 6 and 7) in an analogous fashion to Ti, Y and Zr (ref. 11). Here we show from analyses of a variably altered tholeiite flow that spilitisation may, in some circumstances, affect the REE abundances and their chondrite normalised pattern.

One major obstacle to the study of the relative stability of REE abundances during rock alteration is the rarity of outcrops that show a continuous gradation from a fresh to a highly altered condition. The Bhoiwada section, part of a volcanic sequence on Bombay Island, India, is such an occurrence and allows a test to be made of possible mobility of REE during spilitisation.

The Bhoiwada section exhibits^{12–15} the gradation of a fresh, black, plagioclase-clinopyroxene tholeiite into a green, albite-chlorite-zeolite spilite within a single Deccan flow unit, 30 m thick (Fig. 1). Details of petrography, major and minor element analyses and field description are provided by Vallance¹⁴ and Sukheswala¹². Vallance¹⁴ also presents evidence to show that the section represents one flow unit, part of which may have been subaerial and part subaqueous. The section can be divided into five zones¹⁴. Only zone 5 is pillowed; we have subdivided an outer margin of a pillow into three parts (Fig. 1b). The pillows are often highly amygdaloidal and contain rosettes of laumontite, with prehnite, quartz and calcite. There is a concentration of amygdales immediately below the thin (less than 5 mm thick) black, chlorite-rich rind. Brief mineralogical descriptions for each sample are given with Fig. 2.

REE abundances in powdered rock samples were determined by instrumental neutron activation analysis¹⁶. Accuracy and precision are estimated to be about 4% at the 95% confidence level, for all REE except the Ho data which are about 10%.

REE abundances for the five zones are presented as chondrite normalised diagrams in Fig. 2 (a) and Fig. 3. La/Sm and La/Yb ratios are given in Table 1. For comparison, REE patterns are shown (Fig. 2) for two of Kuno's Japanese basalt types¹⁷, an alkali basalt and nepheline benmoreite from the Dunedin volcano, New Zealand¹⁸, and a tholeiite from the neovolcanic zone in

Fig. 1 a, Sketch of Bhoiwada section and its five zones (after Vallance¹⁴ and Sukheswala¹²); b, Sketch of pillow margin, zone 5.

Fig. 2 REE abundances (chondrite normalised after Haskin *et al.*²⁴) from *a*, Bhoiwada, zones 1-5. Sample descriptions: 1, plagioclase-clinopyroxene-(magnetite) tholeiite. Some phenocrystal plagioclase and clinopyroxene. Intersertal patches of altered glass. 2, Same as 1 except for appearance of small chlorite-filled amygdaloids and chloritised matrix. 3, (open circles) Chlorite-albite-prehnite-spilite. 3Z: Strongly zeolitised spilite. Laumontite-prehnite-quartz amygdaloids within a chlorite-albite matrix. 4, (crosses) Chlorite amygdaloids within albite-chlorite-spilite. 5, (open squares) Core of pillow. Albite-chlorite-prehnite-spilite. Amygdaloids of chlorite and prehnite. All spilites possess relict clinopyroxenes. *b* Fresh recent lavas: ■, Japan—high-alumina basalt (h.a.b.) from Fuji volcano, Mishima and alkali olivine basalt (a.o.b.) from Oki Dogo Island¹⁷. These two basalts are representative of two of Kuno's basalt types. ●, New Zealand—alkali olivine basalt and nepheline benmoreite (n.b.) from the Dunedin volcano, East Otago¹⁸. ◆, Iceland—tholeiite basalt (t.b.) from Askja caldera, neovolcanic zone¹⁹.

Iceland¹⁹. La/Yb ratios are listed for several basalt types from different environments in Table 2.

The marked increase in the concentrations of REE with spiliteisation can be seen easily from Figs 2 and 3. Not only do absolute abundances change but also the La/Sm and La/Yb concentration ratios (Table 1). The observed

Fig. 3 Chondrite normalised REE abundances within a single pillow—zone 5 (see Fig. 1). ◆, black rind; □, core; ●, zeolite-free skin; ○, zeolite-rich skin; ■, 15087B—a pillow skin donated by Vallance.

changes are consistent with the generation of spilites as being a secondary process¹⁴⁻¹⁵. However, it is to be noted that there is virtually no change in the ratios of the values observed in slightly altered and more extensively altered material.

These results have implications for former studies in which REE abundance patterns of altered basalt and spilites were compared with those of fresh rocks. For example, the pattern of a zone 5 pillow alone might have been interpreted as the spiliteised equivalent of an alkali basalt (see Figs 2*b* and 3). The shift in La/Yb ratios

transcends values from numerous basalt types and geological environments (Tables 1 and 2). The variation also mimics natural basalt crystallisation-differentiation patterns. Consequently our results for the specific case of a light REE (LREE) enriched pattern at Bhoiwada indicate that it is unwise to interpret altered basalts as possessing alkaline affinities on the basis of the REE abundances alone.

Two examples of such interpretations are: the REE patterns shown by rocks of a lower Palaeozoic greenstone terrain in West Norway, indicate different degrees of partial melting of the source material for parent magma⁹; and the suggestion⁷ that the genesis of a Mesozoic ophiolite, exposed in central Greece, involved the existence of a tensional rift system. Our data show that an alternative feasible interpretation is that the REE patterns have resulted partly from secondary metamorphic or metasomatic activity. A similar interpretation¹⁰ has been made for some zeolitised Icelandic lavas.

The layer silicates, such as chlorite, and the low-birefringent, very fine-grained matrix in the spilites, could play a significant role in determining the REE abundance patterns. Roaldset and Rosenquist²⁰⁻²² describe chlorite in Quaternary clays of the Numedal area, Norway, as capable of increasing the La content by almost four times, through

540-Myr-old anorthosite complex in the Grenville Province of Quebec, Canada

MASSIF-TYPE anorthosites and related rocks are an important component of the Grenville and Nain structural provinces of the Canadian Shield (Fig. 1), as well as in high grade metamorphic terrains in other parts of the world. There are many outstanding problems in the study of these rocks, not least of which is their age. Most geochronological data have been obtained from the associated granitic rocks of this suite as anorthosite itself contains very little rubidium and zirconium. Because of post-crystallisation deformation, however, the relationship between the anorthosite and the

Fig. 1 The location of the Sept Iles and other major anorthosite complexes in the Grenville and Nain Provinces are shown. The northern boundary fault of the St Lawrence Graben follows the shore line in most of this area.

associated rocks is often tenuous and frequently disputed. Within the Grenville Province metamorphosed rocks believed to be genetically associated with anorthosites have yielded ages ranging from 1,020 to 1,130 Myr (refs 1–4). The high-grade of metamorphism surrounding the Morin and Lac St Jean anorthosites is believed by some researchers to be due to anorthosite emplacement. These 'aureoles' yield Rb–Sr ages^{5,6} of about 1,500 Myr. Anorthosite complexes in the Nain Province are undeformed, and the adamellite of the suite has yielded a U–Pb zircon age⁷ of about 1,300 Myr. Barton⁸ obtained a Rb–Sr isochron age of 1,418 Myr from a digested inclusion in the Nain anorthosite. Here we present geochronological data from the undeformed Sept Iles anorthosite, and show it to be Cambrian in age.

The Sept Iles anorthosite complex is situated on the north shore of the Gulf of St Lawrence, about 800 km north-east of Montreal, on the southern edge of the exposed portion of the Grenville Province. Apart from rare alkalic rocks, ages of Grenville Province rocks exceed 900 Myr. The Sept Iles anorthosite complex is, however, situated on the boundary between the St Lawrence Graben and the Grenville Province, which is the locus of intrusion of alkalic rocks ranging in age from early Cambrian to Cretaceous⁹. Its boundaries are clearly indicated on aeromagnetic maps, and by a substantial positive gravity anomaly measuring approximately 50 km × 70 km. Its host rocks on shore are thought to be a moderately deformed anorthosite. The complex has been considered to be a good example of undeformed Grenville anorthosite¹⁰. The islands have been mapped in detail (S. T. Ahmedali, personal communication) and consist of anorthosite grading upward into well layered gabbro. The gabbro is overlain along a sub-horizontal contact near sea level by granitic rocks ranging from partly layered monzonite near the base to adamellite. The granitic rocks are slightly alkaline in their chemistry and contain alkali pyroxenes and amphiboles. Field relationships show clearly that the more basic members of the suite were only partly consolidated during the emplacement of the monzonite. An age from this unit would therefore date the anorthosite. Verification of this relationship was obtained by isotopic means from more rubidium-rich segregations within the anorthosite itself.

Isochrons have been obtained from a single outcrop of the layered monzonite and from a 500-m section through the adamellite. These yield ages of 538 ± 17 Myr and 552 ± 12 Myr (Fig. 2a, b) (all errors are expressed as single standard deviations). Rb–Sr data have also been obtained

from alkali rich patches within the anorthosite. The contemporaneity of these bodies and the anorthosite is clearly visible in the field, because of the lack of deformation (Fig. 3). The host anorthosite consists of black plagioclase crystals 1 to 4 cm in length, with small amounts of interstitial mafic material. As the pegmatite is approached the grain size of the plagioclase increases, and these large crystals project into the zone of micrographic orthoclase and quartz. These patches are less than 1 m in diameter and are frequently aligned along what are assumed to have been zones of low pressure in the semiconsolidated anorthosite magma. More conventional anorthosite pegmatites also occur in zones between the orthoclase rich areas.

The isochron of Fig. 2c is from two adjacent pegmatites and their host anorthosites. The points define an age of 555 ± 12 Myr and an initial ratio of 0.7036 ± 0.0004 . The second isochron (Fig. 2d) is derived from three samples of a single pegmatite, combined with a single sample from a

Fig. 2 Isochrons from the Sept Iles anorthosite and related rocks. The low initial ratio of (b) could be due to the abundance of xenoliths in this unit. Error bars (single s.d.) were calculated for both variables but are only shown where they exceed the diameter of the symbol. Ages were calculated using $\lambda^{87}\text{Rb} = 1.39 \times 10^{-11} \text{ yr}^{-1}$. a, Monzonite; b, adamellite; c, two adjacent pegmatites; d, three samples of a single pegmatite, combined with a single sample from a nearby pegmatite and the host anorthosite.

nearby pegmatite and the host anorthosite. The points are within experimental error of a line representing an age of 544 ± 6 Myr and an initial ratio of 0.7042 ± 0.0005 .

The initial ratios of these isochrons are consistent with ratios of 0.7039 (s.d. 0.0005) obtained from eight anorthosite and gabbro samples distant from the rare pegmatitic areas.

All ages reported here agree within narrow limits of experimental error, supporting the temporal relationships observed in the field. Granite, syenite, and carbonatite

Fig. 3 The alkali-rich pegmatite shown here is located near the pegmatites used to construct isochron 2c. The large black plagioclase crystals that project into the micrographic zone are clearly visible.

bodies associated with the St Lawrence Graben system yield similar ages^{9,11}. The adamellite of the Sept Iles complex is very similar to some of these rift-related rocks. The location of anorthosite in a rift environment, associated with acidic alkaline rocks, may provide insight into the origin of both these suites. The results also suggest that many anorthosites may be anorogenic, although some may be deformed by later orogenic events.

This work was supported by the NRC and the Geological Survey of Canada. We thank S. T. Ahmedali for introducing us to the region and for providing information on the relationships between the various rock units of the complex.

Phenology of sound-producing arctiid moths and the activity of insectivorous bats

THE lepidopteran family Arctiidae contains a number of species that emit high frequency sounds when tactually stimulated or exposed to the intense hunting cries of insectivorous bats¹⁻³. The sounds are produced as rapidly repeated clicks generated by the buckling action of the row of striae⁴ or microtymbals⁵ on the surface of the modified metepisternum (tymbal)⁶. The sounds seem to act as aposematic cues to discourage nocturnal, ultrasonically sensitive predators such as bats⁷. Flying bats will avoid otherwise palatable prey (mealworms) when accompanied by the recorded sounds of arctiid moths². If bats play an important role in the evolution of sound production in arctiids then bat activity levels in an area should influence the phenology of acoustically active arctiids there. By examining the incidence of some silent and sound-producing Nearctic arctiids and its relationship to ambient levels of bat activity, some of those influences can be demonstrated.

During the summers of 1975 and 1976, I collected moths from four ultraviolet lights located at the Queen's University Biology station near Chaffey's Locks, Leeds County, Ontario, Canada. The lights were inspected twice a night and any arctiids captured were immediately identified and tested for acoustic activity using a Brüel and Kjaer quarter-inch condenser microphone (type 4135) and measuring amplifier (type 2606) with a Tektronix 5103N storage oscilloscope⁷. Bat activity was monitored at the same location using an automated ultrasonic sensing system with detectors tuned to 40 kHz (ref. 8) directed over a lake where bats commonly fed. This location ruled out the possibility of detecting other sources of biological ultrasound (for example, insects).

Of the 24 arctiid species captured at the lights, 17 produced sound under light to heavy tactile stimulation (Table 1). Although the sounds generated by the moths were

extremely variable in amplitude-time patterning, frequency and intensity^{7,9} the degree of tactile stimulation required to elicit sound production was relatively constant within the categories listed in Table 1 for each species. A trend which soon became obvious was the timing of the emergence of silent and sound-producing species. During both summers, it was the silent species that appeared in the spring, and it was not until mid-July that a substantial proportion of moths caught at the lights were sound-producing species.

A comparison of the ambient bat activity levels in the area with the incidence of sound-producing arctiids (Fig. 1) reveals a close relationship between the two observations. A closer look at two genera lends insight into this relationship.

Phragmatobia (Stephens) includes two similar species that were captured at the study site: *P. assimilans* (Walker) and *P. rubicosa* (Harris). *P. assimilans* is a spring moth emerging early in May and disappearing before June. *P. rubicosa*, on the other hand, is a summer species, emerging in late July and remaining until August. *P. rubicosa* is an acoustically active species and will emit sounds under moderate tactile stimulation; its congeneric, *P. assimilans*, however, is silent. Scanning electron micrographs of the tymbal surfaces (Fig. 2) reveal that both species possess microtymbals but the band appears less defined in *P. assimilans* and may be vestigial.

The two species of the genus, *Hypoprepia* (Hübner), *H. fucosa* (Hübner) and *H. miniata* (Kirby) are also superficially similar in size and coloration¹⁰ and are also separated in their emergence times. *H. fucosa* appears from July to mid-August, whereas *H. miniata* appears somewhat later. Both species in this genus, however, emerge during periods of high bat activity and produce sound when lightly stimulated.

Animals exposed to unique forms of predation may develop predator-specific defences¹¹ that act directly on the particular characteristic of the relevant predator. Thus, the high frequency emissions of certain arctiids may be

§Degrees of stimulation similar to Blest¹: light involves merely touching the moth; moderate indicates the moth had to be shaken or prodded; and heavy indicates that very severe handling was required.

Fig. 1 Relationship between summer activity levels of insectivorous bats and phenology of sound-producing arctiid moth species. Bat activity (□) is recorded as 'bat passes'; incidence of acoustically active arctiids (■) are the averages per quarter month.

signals intended for the ultrasonically sensitive ears of predators such as bats. Since the maintenance of such specific defences should be dependent on the level of threat posed by the predators concerned, species exposed to lower levels of activity of these predators should not possess the defences of individuals more severely threatened. Therefore, the high proportion of silent arctiids present in the spring may be a response to the lower levels of bat activity at these times.

Phragmatobia offers an intriguing example of this relationship. *P. assimilans* is not only a silent species, similar to its acoustically active summer relative, *P. rubicosa*, but also possesses a tymbal structure which suggests that *P. assimilans* may have been a sound-producing species at one time. By shifting its emergence time to spring and thus avoiding the time of high bat activity (although this may not have been the original reason for the shift), *P. assimilans* no longer required a functional tymbal and now retains only a vestigial form of the organ. *Hypoprepia*

Fig. 2 a and c, Acoustically active summer arctiid, *P. rubicosa*, and its tymbal. b and d, Silent spring species, *P. assimilans*, and its non-functional tymbal with what appears to be a vestigial micro-tymbal band. Upper scale indicates 40 mm; lower scale indicates 1 mm.

illustrates a similar situation, the important difference being that both species emerge during high levels of bat activity and both produce sound.

Silent species that persist into or emerge in mid-summer (for example, *Spilosoma virginica* (Fabricius) and *Estigmene acrea* (Drury)) may be less vulnerable to bats for a variety of reasons. *E. acrea* is a very large arctiid and this may afford it sufficient protection from most hunting bats. Since arctiids will perform aerial evasive tactics in the presence of echo-locating bats¹², there may be a greater adeptness at this and other anti-bat defences that have allowed certain silent arctiids to exist in times of high bat activity.

As bats are not the only ultrasonically sensitive insectivorous predators that arctiids must contend with, it is likely that the ambient summer levels of non-Chiropterans (for example, *Peromyscus*) may also exert an influence on the phenology of sound-producing arctiid species. The diverse interactions that arctiids have with their predators are poorly understood and must be clarified before some of the puzzling problems associated with comprehending this unique form of defence can be dealt with.

Survival value of fever in fish

THE phenomenon of behavioural fever, manifested as an increase in preferred temperature following injection of live or killed bacteria, or other pyrogenic substances, has been demonstrated in bony fishes¹⁻³, amphibians^{4,5}, reptiles⁶⁻¹⁰, and mammals^{11,12}. Ectothermic vertebrates, including some newborn mammals¹¹, are unable to increase their body temperatures much above ambient by physiological means, and so are largely limited to behavioural thermoregulation by selecting favourable temperatures in their environment. The behavioural febrile response of a lizard, *Dipsosaurus dorsalis*, has been shown to have adaptive value^{8,9-10} in conferring increased survival during infection by the Gram-negative bacterium *Aeromonas hydrophila*. *A. hydrophila* is pathogenic to bony fishes, amphibians and reptiles, causing haemorrhagic septicaemia. All three classes show similar (1-5 °C) elevations in preferred temperature in response to injection of this bacterium¹⁻¹⁰. The absolute preferred temperatures, however, both normal and febrile, differ considerably among these vertebrates. The preferred temperatures of lizards such as *D. dorsalis* (about 40 °C) are quickly lethal to most fishes and amphibians. We report here that fever significantly

enhances survival of goldfish, *Carassius auratus*, at febrile temperatures about 10 °C lower than those of *D. dorsalis*, after injection with live *A. hydrophila*.

To study the thermoregulatory behaviour of fish we used an electronic shuttlebox device which allows a fish to control water temperatures and, thereby, its body temperature, by its movements between chambers monitored by photocells^{13,14}. The behaviour of a fish in this device is equivalent to seeking out preferred temperatures in its natural environment¹³. At least some fishes have been shown to exhibit circadian changes in preferred temperature^{14,15}. Specifically, the goldfish exhibits a diel rhythm of preferred temperature with a pre-dawn peak (W. W. R., M. E. Casterlin, J. K. Matthey, S. T. Millington and A. C. Ostrowski, in preparation). Accordingly, for this study we pooled data for 24-h periods¹⁻⁴, to simplify presentation of the data by showing changes in mean preferred temperature for 24 h before and after injection with bacteria.

Earlier work with largemouth blackbass (*Micropterus salmoides*) and bluegill sunfish (*Lepomis macrochirus*) indicated a mean febrile increase in preferred temperature of 2.6 °C after injection with killed *A. hydrophila*. We therefore used a nominal febrile elevation of 2.5 °C to represent a typical fever in fish. We tested 10 goldfish in our thermoregulatory apparatus (Ichthyotron)¹³. These had a mean baseline (afebrile) preferred temperature of 27.9 °C, which agrees well with a previously published final preferendum value of 28.1 °C for *C. auratus*^{16,17}. Using a nominal 28 °C baseline temperature and the nominal 2.5 °C febrile elevation value, we tested three groups of 25 goldfish at fixed temperatures of 25.5 °C, 28.0 °C and 30.5 °C for 72 h. These represented, respectively, hypothermic, normothermic and febrile temperatures. The 75 goldfish, weighing about 4 g each, were injected intraperitoneally with 0.1 ml of sterile pyrogen-free fish saline containing 2×10^6 live *A. hydrophila* cells.

Goldfish maintained at a febrile temperature of 30.5 °C (Fig. 1) had the highest survival rate (84%), while only 64% survived at 28.0 °C and 24% at 25.5 °C. A control group of 10 fish, injected only with sterile saline, all survived at 25.5 °C. Another 10 fish injected with live *A. hydrophila* and allowed to thermoregulate in the shuttlebox attained an unexpectedly high mean febrile preferendum of 32.7 °C, a mean increase of 4.8 °C. The circadian rhythm of preferred temperature was maintained around the higher set-point. The high 4.8 °C febrile increase may have been due to multiplication of the live bacteria, resulting in a higher weight-specific dosage in these goldfish, which were smaller than the bluegills and bass tested previously¹ with killed bacteria. It may be relevant that the ultimate upper

incipient lethal temperature of goldfish is unusually high¹⁶ (about 41 °C) for fish—about 6 °C higher than that of bluegill and bass. None of the 10 febrile thermoregulating goldfish died, so the 32.7 °C temperature afforded even greater protection (Fig. 1) than did the nominal febrile temperature of 30.5 °C.

To examine the effect of temperature on growth rate *in vitro* of *A. hydrophila*, we grew cultures at 28, 30 and 33 °C (Fig. 2). We determined growth curves by inoculating 100 ml of glucose nutrient broth or brain-heart infusion broth with 0.1 ml of a 14 h broth culture; at 1–2 h intervals the cultures were plated and turbidometric readings made. There was no significant difference among the growth curves at the three test temperatures (Fig. 2), so the survival value of the fever apparently cannot be attributed to an effect of temperature on bacterial growth within the range of temperatures selected by goldfish. This is also true for lizards (*D. dorsalis*) at still higher temperatures⁵.

Fig. 2 Growth curves for three *A. hydrophila* cultures *in vitro* at 28 °C (□), 30 °C (○) and 33 °C (●).

Immunological responses of fishes and other poikilothermic animals have been shown to be significantly affected by temperature^{18,19}. The critical temperature levels are species-specific¹⁸, and vary considerably among classes¹⁹. For example, the normal body temperature of the lizard *D. dorsalis*⁵⁻¹⁰ exceeds even the febrile temperatures of the fish species studied, and indeed would be lethal to most fishes and amphibians. It thus seems that the absolute febrile temperature *per se* is less important than the febrile elevation above temperatures normal for the species.

Similar enhancement of survival during a viral disease by elevation of the water temperature has been reported for sockeye salmon, *Oncorhynchus nerka*²⁰. Mortality was prevented at 18 °C, which is 3.5 °C above the 14.5 °C normal preferred temperature of this cold-water salmonid species¹⁷. Amend²⁰ did not study behavioural responses to the virus infection. The virus was not destroyed by the 18 °C temperature, and enhancement of some critical hormone or enzyme activity was postulated as the cause of the increased survival²⁰. Another possibility is that increased phagocytosis could result from increased vascular permeability leading to greater mobility of the antigen-processing cells in the early stages of infection. It has also been suggested²¹ that there may be a relationship between temperature-dependent toxic effects of various substances and their effects on preferred temperatures of fishes, which might serve to reduce mortality.

Survival of infection can apparently be enhanced by fairly short-term increases in temperature, as the heliothermic *D. dorsalis* is able to thermoregulate only during the day, with body temperatures dropping to ambient

Fig. 1 Survival curves for goldfish at four temperatures after intraperitoneal injection with live *A. hydrophila*. Three groups of 25 fish each were held at fixed temperatures of 25.5 °C (○), 28.0 °C (●), and 30.5 °C (△); 10 fish (▼) were allowed to behaviorally thermoregulate at a mean temperature of 32.7 °C.

(12 °C) at night¹⁰; the daytime elevation of body temperature is apparently sufficient to enhance survival of infection⁸⁻¹⁰. Similarly, our febrile infected goldfish experienced no mortality following removal to holding tanks at room temperature (23 °C) after thermoregulating for several days at elevated temperatures. Avtalion¹⁸ has shown that after fish are allowed to develop a positive immunological memory at a high temperature, they are then able to produce antibodies even at low temperatures. It thus seems likely that some initial step in the immune response is enhanced by a febrile increase above the normal preferred temperature of a species, and that this is effective even if the febrile temperature is not constantly or indefinitely maintained.

We thank Drs M. J. Kluger and E. Satinoff for reviews.

Soluble fragments from fungal cell walls elicit defence reactions in crayfish

ALTHOUGH most fungi that parasitise arthropods are relatively harmless, many can penetrate different types of cuticle¹. Thus active defence mechanisms presumably operate *in vivo*. In crayfish, for example, resistance to fungal penetration is associated with melanisation of the cell wall of the fungus by host phenols and phenoloxidase². This constitutes a system for recognising the invading organism at different levels, from the cuticle surface inwards³. Melanisation in insect blood, due to phenoloxidase activity, is also induced by the presence of cells or cell walls of fungi^{4,5}. Crayfish phenoloxidase in cuticle and blood is highly and specifically activated in contact with the purified hyphal cell walls of most fungi but not with other plant cell walls⁶. We have now found that soluble β -1,3-glucans from fungal cell walls activate the enzyme and may serve as specific elicitors of recognition in crayfish of invading fungal parasites.

Haemolymph was bled from the abdominal haemocoel of crayfish, *Astacus astacus*, using a hypodermic needle (0.8 mm diameter, 21 gauge). Because phenoloxidase is released by blood cells during clotting, cell free serum from pooled, clotted blood was used as a source of enzyme⁶. The clot was homogenised and centrifuged for 10 min at 3,000g. The phenoloxidase activity of the serum obtained was determined in a mixture of 0.2 ml serum, 0.1 ml dihydroxy-

phenyl alanine (dopa, 4 g l⁻¹), and 0.2 ml 0.01 M sodium acetate buffer, pH 5.2, with or without dissolved cell wall extract. The mixtures were incubated at room temperature, about 22 °C, in an open microscope slide cuvette⁷ for about 30 min. Before addition to the serum mixture the cell wall extract was preheated to 100 °C for 20 min to disperse aggregates. After covering the slide cuvette with a coverslip the activity of phenoloxidase on dopa was calculated from the increase in absorbance at 480 nm using a Shimadzu MPS-50 L photometer⁷.

Zymosan (purified cell walls from *Saccharomyces cerevisiae*) activated crayfish phenoloxidase, especially in regions close to the cell wall surface (Fig. 1). This effect is similar to that seen in fungal cell walls purified in alcoholic KOH⁸. Furthermore, the supernatant from centrifuged suspensions of Zymosan or purified cell walls (even after six washings) of different fungi strongly activated phenoloxidase. Apparently, water-soluble fragments with activating capacity were released in very small concentrations from the solid cell walls.

In the present work we used the supernatant (containing the yeast cell wall activator) from a 1% suspension of Zymosan suspended in 0.01 M sodium acetate, pH 5.2. The molecular weight of the activator was estimated on a column (26 mm $\times$ 550 mm) of Sephadex G 200, using acetate buffer at pH 5.2. Blue dextran 2000 (Pharmacia), bovine γ globulin and trypsin (both Sigma) were used as standards. When compared with the standards, the apparent molecular weight of the activator was between 10⁵ and 10⁶; small amounts of material with a molecular weight between 3 $\times$ 10⁴ and 10⁵ were also present. It seems that the elicitor is not a distinct molecule but consists of macromolecules or molecular aggregates of varying size.

Most elicitor activity was not bound to a cation (SP-Sephadex C 25), nor to an anion exchange resin (DEAE-Sephadex A 25) when the material was dissolved in and eluted with 0.01 M sodium acetate buffer, pH 5.2, and 0.01 M Tris-HCl buffer, pH 8.2, respectively and was apparently not charged to any detectable extent at these pH values.

The activator solution (from 1% Zymosan) contained about 0.4 g of dry material per l (desiccation at 100 °C for 3 h). It activated phenoloxidase even when diluted 10,000-fold. Elicitor activity could therefore be measured at least down to a concentration of about 10⁻¹¹ M.

The yeast cell wall elicitor was also pretreated at 22 °C for 1-24 h with different hydrolytic enzymes (0.2 mg ml⁻¹) to investigate the possibility that the elicitor molecules

Fig. 1 Zymosan activation of phenoloxidase of the cell free serum of crayfish. In the presence of a substrate, dopa, the cell walls thereby become melanised (dark). a, Dopa added; b, dopa not added. ($\times$ 1,000).

could be inactivated (Table 1). The samples were heated (100 °C, 20 min) to destroy lytic enzyme activity and disperse aggregates before addition to the test mixture containing serum and dopa. Results were compared with the corresponding heated control sample containing the hydrolytic enzyme alone. As *Saccharomyces* cell walls contain mostly β -1,3-glucans⁸, it was not surprising that endo- β -1,3-glucanase affected the soluble cell wall fragments. This enzyme increased the activating capacity of the cell wall fragments (Table 1), especially after short exposure. Exposure for several days, however, did not destroy the activator substance or significantly decrease its molecular weight. Owing to the enzyme activity the number of active groups on the glucans was probably increased by exposing new, activating groups derived from the splitting of the large molecules. Digestion of the soluble fraction from 1% Zymosan suspension for 0.5 and 3 h with endo-glucanase followed by vacuum dialysis showed that none of the active molecules formed by hydrolysis had a molecular weight less than 20,000.

After long treatment with endoglucanase (Table 1) the additional, activating groups, but only these, were apparently digested and destroyed by the enzyme. Exo- β -1,3-glucanase, however, almost completely destroyed all the activating capacity of the glucans, suggesting that chains of β -1,3-linked glucose residues are involved.

Proteases had little or no effect and did not change the molecular weight of the bulk of the activator. Treatment with cellulase increased the activating effect considerably (Table 1). Traces of β -1,3-glucanase activity may be responsible for this, unless cellulosic components were also present in the glucans.

Since β -1,3-glucans seem to be involved in the activation, laminaran, a sparsely branched β -1,3-, β -1,6-glucan (from the alga *Laminaria hyperborea*) with an overall degree of polymerisation of about 30 glucose units, was also tested against the crayfish serum. At concentrations of 4×10^{-4} to 2×10^{-3} M this compound strongly inhibited phenoloxidase activity but at 4×10^{-6} to 10^{-6} M it was stimulatory. Activation could be detected down to about 10^{-7} M. The reason for the inhibitory effect at the higher concentrations is not yet known.

Pretreatment of 0.1% laminaran for 24 h with endo- or exo- β -1,3-glucanase destroyed activating capacity (Table 1).

Table 1 Effect of soluble *Saccharomyces* cell wall fragments and of laminaran on crayfish phenoloxidase after pretreatment with lytic enzymes

Pretreatment	Increase in activity of phenoloxidase*	
	Zymosan (%)	Laminaran (%)
None	600 (0.66)†	160 (0.18)
Pronase	600 (0.66)	—
Trypsin	650 (0.72)	—
Cellulase	900 (0.99)	—
Endo- β -1,3-glucanase	800‡ (0.88)	0 (0)
Exo- β -1,3-glucanase	60 (0.07)	0 (0)

Pretreatment of 1 mg ml⁻¹ laminaran (Koch-Light) and of the soluble fraction (0.4 mg substance per ml) from a 1% suspension of purified *S. cerevisiae* cell walls (Zymosan, Koch-Light) was carried out at pH 5.2 in 0.01 M sodium acetate buffer for 24 h. Lytic enzymes used (0.2 mg ml⁻¹) were: Pronase (Sigma), trypsin (Difco), cellulase (S173, from *Trichoderma viride*, having traces of β -1,3-glucanase activity) endo- β -1,3-glucanase (S176G, from *Rhizopus arrhizus*) and exo- β -1,3-glucanase (highly purified). Phenoloxidase activity against dopa was measured photometrically. Percentage increase in activity after addition of tenfold diluted, activating cell wall material or pretreated cell wall material is given.

*Measured after 30 min incubation. Phenoloxidase activity in absence of activating cell wall glucans was equivalent to A_{480} of 0.11 in the assay system.

†Figures in parentheses are A_{480} values in assay.

‡After 30 min pretreatment, 1,000% increase. After 3–5 d, increase was about 600%.

Thin-layer chromatography of the enzyme digests on silica gel (*n*-butanol/ethanol/water: 5/3/2) showed complete degradation of the glucan into mono- and disaccharides after 3 h of incubation with the enzyme.

Cell walls from many other fungi also activate the phenoloxidase from crayfish⁹. We treated activator-containing extracts from cell walls of *Polyporus annosus*, a basidiomycete, and *Aphanomyces astaci*, an oomycete, with the exo-glucanase as above. In both cases the activating capacity was destroyed indicating that the elicitor is a β -1,3-glucan and may be a general characteristic of most fungi.

Among vertebrate parasites fungi are less common than bacteria. The reason for this is not known and the vertebrate immune system cannot fully explain the discrepancy⁹. It is possible that soluble and chemically related cell wall fragments from different fungi, such as the elicitors described here, are also involved in the nonspecific recognition of fungi by vertebrates. It is interesting that a fungal β -1,3-glucan has been claimed specifically to induce anti-tumour activity in the mouse¹⁰.

Albersheim *et al.*^{11,12} have characterised fungal cell wall fragments which elicit host response in bean tissues, and the similarity with the fungal elicitor active in crayfish is striking. It is therefore tempting to speculate that most fungi cannot avoid producing 'warning signals' which are similar in different fungal groups and recognised by both plants and animals.

We thank Dr Sverker Bernander for critical revision of the manuscript and Mr Ragnar Ajaxon for technical assistance. Cellulase and endo- β -1,3-glucanase were gifts from E. Reese and exo- β -1,3-glucanase was from S. Kirkwood.

Action of juvenile hormone mimics on the regulation of larval-adult and alary polymorphism in aphids

It has often been suggested that the development of the apterous and alate morphs of aphids is controlled by the corpus allatum (CA) and is therefore regulated by the same endocrine system that controls larval-adult development in monomorphic insects^{1–6}. Research on other polymorphic species, including the honey bee and termites, has shown that this function is compatible with the cyclical production of juvenile hormone (JH) during larval ecdyses as the morph-determining action of the hormone may be confined to a certain strictly defined critical period or may depend on specific hormone concentrations in the blood^{7,8}. In aphids the prenatal determination of late embryos as presumptive apterae has been attributed to high JH titres in the maternal haemolymph^{4–6}; and the subsequent realisation of the morph characters has also been thought to

Fig. 1 *Megoura viciae*: a, normal adult aptera; b, normal alata in fourth (last) larval instar; c, normal adult alata; d, fifth-instar larval-adult intermediate produced by topical application of 10^{-3} μ g ZR-512 to a third-instar alate larva. This individual did not undergo a further ecdysis. e, Fifth-instar supernumerary alate larva showing maximum juvenilising effect. 10^{-2} μ g ZR-512 was applied to the third-instar alata. f, Sixth-instar larval-adult intermediate resulting from the ecdysis of a high grade supernumerary larva (as in e), produced by treating a third-instar alata with 10^{-2} μ g ZR-512.

involve enhanced CA activity in the early instars of the developing larva^{2,3}. The evidence, which has been based on measurements of CA volume and on the effects of topically applied JH is nevertheless conflicting^{9,10}. The results reported here show that the intermediate and terminal forms produced by the application of juvenoids to developing alate aphids are unlike those resulting from authentic

apterisation initiated either by the absence of crowding or by exposure to long photoperiods. This does not support the persuasive argument that the possession of certain apparently juvenile characters by the 'neotenic' apterae (for example, the wingless condition of the adult) is a reliable indicator of JH involvement.

In early experiments with the vetch and bean aphid *Megoura viciae*, cecropia extracts with relatively slight JH activity were applied topically to alateform larvae in their penultimate (third) larval instar^{2,3}. After an externally normal ecdysis to the fourth instar, these individuals developed into adults with stunted wings, a reduced pterothorax and an abdominal pigment pattern resembling the adult aptera rather than the adult alata (Fig. 1a, c and d). The use of more potent synthetic JH mimics, however, has shown that this effect does not represent progress towards the apterous morph. After treatment with a saturating dose of JH mimic third instars develop into a supernumerary fifth-instar alate larva with unmistakable wing pads and a completely unsclerotised pterothorax (Fig. 1e). In addition, the genital opening remains closed and the ocelli are often suppressed. A further ecdysis follows. The few sixth-instar aphids that can extricate themselves from the old cuticle are often still somewhat juvenile in appearance (Fig. 1f). These more extreme features, which have been observed in several species^{5,11}, indicate that the juvenilising effect is similar to that in many other insects¹². It is not surprising therefore that other aphid morphs including the aptera and the wingless ovipara respond in a comparable manner^{13,14}.

It is less certain, however, whether juvenoids also affect morph determination, because this event occurs much earlier. In *Megoura*, for example, the morph type is controlled maternally just before birth¹⁵. To test this point, 1.0- μ g quantities of the juvenoids ethyl 3,7,11-trimethyl-dodecadienoate (ZR-512) (Zoecon), methyl 10,11-epoxy-farnesoate (C16-JH) (Eco-Control) or the Law-Williams (L-W) chlorinated farnesoate mixture¹⁶ were applied topically to the abdomen of parent apterae prepared as alata-producers by crowding them together¹⁷. Although all these growth regulators produce a maximum morphological response in the third-instar alata at a dose of only 10^{-2} – 10^{-3} μ g, the treated adults continued to produce alate

Fig. 2 *Aphis fabae*: a-d, range of forms produced by topical application of a JH mimic (Law-Williams) to second and third-instar gynoparae. Examples of four of the five arbitrary response categories are illustrated. a, Normal adult gynopara, untreated: 0% morphological effect (ME). b, Wings curled: 25% ME. c, Wings intermediate, pterothorax weakly sclerotised, large wax patches present: 75% ME. d, Maximal effect. A fifth-instar supernumerary larva with large larval wing pads and conspicuous wax patches: 100% ME. e-h, Range of forms produced by exposing presumptive gynoparae reared in short days to two long photoperiods during the first 2 d of development. The five response categories differ from the above. Examples of four are shown. e, Normal gynopara: 0% ME. f, Intermediate adult with small wing pads: 50% ME. g, Intermediate adult with some thoracic sclerotisation but no wing rudiments: 75% ME. h, Adult showing complete apterisation: 100% ME. Aphids placed in the 50% ME category in the JH series (not shown) have crumpled wings, partially obliterated sutures between the thoracic sclerites and small wax patches. Those assessed at 25% ME in the long day series have half-expanded wings but are otherwise normal alates.

progeny when subsequently isolated on bean seedlings (*Vicia faba*). Apterous-producers, isolated before the final moult, were also unaffected by JH treatments and yielded only apterae. In another experiment, the 1-d-old progeny of crowded parents were sprayed with an acetone solution containing 0.5 µg of L-W mixture (sufficient to ensure a maximum response in groups of third-instar alateform larvae). The proportion of insects developing as apterae was not increased. There was therefore no indication that these JH mimics either influenced the morph-determining process in the parent or modified the alate character of the neonatal progeny immediately after determination.

The winged gynoparae of a host-alternating species such as the black bean aphid *Aphis fabae* have two advantages as experimental subjects. First, it is certain that every first-instar larva is a presumptive alata, provided the parent has developed in short days (12 h light: 12 h dark) at 15 °C. Second, the alate condition of the first-instar gynoparae is partially or completely suppressed by exposure to a threshold number of long days (16 h light: 8 h dark) during the first and second instars. The intermorphs and extreme forms can then be compared with the intermediates produced by JH treatments.

The range of morphological effects produced by JH is shown in Fig. 2. As in *Megoura*, the extreme forms are near-perfect fifth-instar supernumerary alate larvae with large wing pads, an unsclerotised pterothorax, a closed genital canal and, in this species, conspicuous larval wax patches (Fig. 2d). These juveniles invariably undergo an additional ecdysis. An assay based on these and other characters has been used in assessing the morphological effect (ME) of a JH mimic (0.5 µg L-W in acetone) when applied as an atomised spray to developing colonies of gynoparae, each comprising about 100 individuals. Figure 3 shows that the presumptive gynoparae display relatively little sensitivity in the first day or two of post-natal development, the single application of mimic again producing its greatest effect in the third instar (day 7). In contrast, exposure to two consecutive long photoperiods is maximally effective during the first 2 d of development (Fig. 3). As a result of this early treatment 67% of the presumptive gynoparae continued to develop as normal alate morphs (Fig. 2e), 8% developed as intermediates, some with small wing pads (Fig. 2f), while 25% developed as authentic apterae

Fig. 3 Time of responsiveness to treatments influencing juvenile-adult and apterous-alate characters in gynoparae of *Aphis fabae*. —, Response to a single application of L-W juvenoid when applied at constant dose on different days of larval development. — — —, Response to two long days applied on the days indicated by the photoperiod bars. The response index is calculated as $\Sigma (ME \times n)/N$, where ME is the percentage morphological effect, n the number showing this grade of response and N the total number of individuals.

without wing vestige or thoracic sclerotisation (Fig. 2h). Moreover, the intermediates and apterae gave birth to parthenogenetic daughters (virginoparae), whereas the unchanged alatae produced oviparous progeny as would a normal gynopara. Neither the intermediates nor the completely apterised aphids underwent supernumerary ecdyses. These results show that juvenilising JH treatments and photoperiodically controlled apterisation are maximally effective at different times during larval development and give rise to terminal morphs which differ both in their external form and in such physiological attributes as type of germarium and ecdysis pattern. This evidence suggests that the control of wing polymorphism, whether vested in the parent (*Megoura*) or in the developing larva (*A. fabae*), is not mediated by JH.

Aphids that have been determined as alata-producers by crowding give birth to a small number of progeny when decapitated^{18,3}. These are invariably apterous. The same effect can also be produced in *Megoura* by sectioning the central nervous system at the level of the suboesophageal ganglion and by other treatments which would not be expected to affect CA activity. These include the exposure of the parent to CO₂ anaesthesia for 30 s, and the amputation of the distal extremities of the legs. The latter effect, which is not produced by other comparable injuries, such as antennal amputation, seems to be correlated with the removal of certain whip-like trichoid sensilla adjacent to the eversible tibial climbing organ. Evidently, the loss of the normal sensory input to the thoracic ganglion both releases the parturition reflex from inhibition and elicits the morph change in the fully developed embryo. These considerations suggest that the effector is neural, but there is as yet no evidence that the control mechanism involves a blood-borne hormone.

Growth and differentiation of a primitive nervous cell line after *in vivo* transplantation into syngeneic mice

In vitro study of nerve cell differentiation has been primarily concentrated on the examination of cell lines that, at least partially, express terminal steps of differentiation. The isolation and characterisation of precursor populations would be an aid to further understanding of nerve cell differentiation. I present here evidence for a clonal line of such a nerve cell precursor type which, after *in vivo* passage, is able to give distinct neuronal phenotypes. These phenotypes are potentially lineage related, and show qualitative

Fig. 1 Diversity of tumour clones. Phase contrast photographs of four hypothalamic clones issued from a tumour of the primitive F7 cells. *a*, A primitive tumour clone. *b*, A newly differentiated cell type (4-3). *c* and *d*, Two neurosecretory cell types as compared to C7 clone's morphology¹. Tumour was sterily excised, finely minced with scissors and then mechanically disrupted with a Pasteur pipette. Cells and small aggregates were plated in 30 ml Falcon plastic culture bottles containing 2-3 ml of Ham F10 medium GIBCO supplemented with 15% heat inactivated horse serum, 2.5% foetal calf serum, 1.5% of 200 mM L glutamine, penicillin (50 IU ml⁻¹) and streptomycin (50 µg ml⁻¹). Cells were grown in an atmosphere of 10% CO₂ 90% air.

differences in the expression of their hypothalamic neuronal function.

Clonal cell line C7 isolated from primary cultures of 14-d-old mouse hypothalamus embryo (A/J) after SV 40 transformation initially retained the capacity to form neurophysin and vasopressin¹, a function unique to some hypothalamic neurones *in vivo*. After several passages however, some cells lost the capacity to synthesise neurophysin and vasopressin. Subclones of the original C7 line were isolated and morphologically, histochemically and immunologically characterised. The primitive nature of one of these clones, F7, derived from such neurosecretory cells, has been tentatively established on the basis of its ultrastructural features and its negative response to all of the tests that were used to identify neurosecretory cells².

If it were possible to demonstrate that a reversible switch from this primitive phenotype F7 back to the differentiated one had occurred, it would give a means of determining whether F7 is a precursor cell antecedent to a definitive neurone; although such a reversible switch has not been observed *in vitro*, this differentiation could be initiated by passage of these primitive nerves through syngeneic mice. The proliferating cells originating from these primitive nerve cells, after transplantation in mice, give rise to tumour cell populations containing both primitive and differentiated cells, as defined by the presence of immunoreactive neurophysin and β -glucuronidase activity.

The primitive nerve cell clone F7 (10⁷ cells) was injected subcutaneously into male A/J mice. Tumours arose after a latent period of 5-10 d. The ability of such transformed cells to proliferate was surprising in view of the fact that the original C7 neuronal type was unable to produce tumours in the same conditions. These tumours were excised and cultivated. Primary cultures were maintained for about 6 weeks in the same flask before cloning and medium was changed by half every 2-4 d. Cells originally plated grew into three distinct morphological types (Fig. 1*a-d*) among which one type was predominant (type 1*b* in Fig. 1). Colonies of these three distinct phenotypes were dissected out with a 10 µl Pedersen micropipette, scraping only the centre of the colony to get clean cell populations.

The first resulting homogeneous population of cells grew in a non-overlapping monolayer, with a division time of 12-16 h (Fig. 1*a*). The model chromosome number of the cells was the same as for the original F7 clone (70

chromosomes). This population grew as a stable line. The Gomori's paraldehyde fuchsin and β -glucuronidase histochemical reactions used before to identify the neurosecretory cells were consistently negative on these primitive cells². The immunocytochemical detection of neurophysin using bovine neurophysin I and II antisera also gave negative results. These cells closely resembled the originally inoculated F7 cells.

The second class of cells were very refractile and interconnected by long narrow processes; they had a division time of about 24 h (Fig. 1*b*). These cells were positive for the two histochemical markers of neurosecretory cells: the Gomori's paraldehyde fuchsin and β -glucuronidase reactions (Table 1). They gave a positive immunocytochemical reaction for neurophysin using bovine neurophysin I antiserum (Fig. 2). They gave a negative reaction using bovine

Fig. 2 Immunocytochemical staining with Ab-NI (1/50). *a*, A newly differentiated tumour cell clone (4-3). *b*, A primitive tumour cell clone (PT). ($\times 300$.)

neurophysin II and vasopressin antisera, however (Table 1). These cells were unstable in the culture conditions—4 to 5 months after the excision of the tumour corresponding to about 17-20 subcultures, the level of intracellular neurophysin began to decline as indicated by the immunocytochemical detection. At the same time, these cells started to divide faster, and progressively took the phenotype of the originally fast dividing inoculated F7 cells.

A third type of cell could be identified among the heterogeneous population derived from the tumour: a neuronal refractile cell type (Fig. 1*c* and *d*) closely resembling the

Table 1 Results of the cytochemical and immunocytochemical staining of the primitive tumour cell type and the newly differentiated tumour cell type, as compared to the original clones (C7 and F7)

Clone	Gomori's paraldehyde fuchsin	β -glu- cunonidase	Ab N I 1 : 50	Ab N II 1 : 10	Ab LVP 1 : 10
Tumour Primitive type (PT)	—	—	—	—	—
Differentiated type (4-3)	++	++	++	—	—
Control neuro- secretory clone (C7)	+++	+++	+++	+++	+++
Primitive clone (F7)	—	—	—	—	—

Gomori's paraldehyde fuchsin staining and cytochemical detection of β -glucuronidase were as previously described². Neurophysin and vasopressin were localised using the peroxidase-labelled antibody technique with antibodies against bovine neurophysin II (Ab-N II), bovine neurophysin I (Ab-N I) and Lys-vasopressin (Ab-LVP). Cells grown in plastic dishes were treated according to Tougaard *et al.*⁷. The specificity of the reaction was tested by using normal rabbit serum. Rabbit antiserum to bovine neurophysin II was specific for neurophysin II and cross-reacted very poorly with bovine neurophysin I⁸. A dilution of 1/10 was used. Rabbit antiserum to bovine neurophysin I cross-reacted slightly with N II (ref. 9). A 1/50 dilution was used. Anti-lys-vasopressin serum was obtained in rabbits immunised with vasopressin coupled to charcoal. A 1/10 dilution was used.

neurophysin-vasopressin synthesising C7 clone¹. These cells grew in a dispersed state, and the number of colonies of such type was small as compared to the other types. Their division time was about 2–3 d. They were rapidly overgrown by other much faster dividing type of cells and they could not be dissected or subcultured. On the basis of their morphological analogy with the other neurophysin-vasopressin clones already isolated², and their slow growth rate as compared to the fast growth rate of the F7 type clones, they may represent the neurophysin-vasopressin synthesising cell class.

In summary the primitive nerve cell line F7, when injected subcutaneously into syngeneic mice, gives rise to tumours which after subculture contain not only primitive cells but also a new type of differentiated cells. These newly differentiated cells can be distinguished from primitive cells on the basis of their morphological and growth rate alterations, their neurophysin content, and their positive reaction towards β -glucuronidase activity, a neurosecretory cell marker *in vitro*³. These cells which contain neurophysin but are negative with a vasopressin antiserum may correspond to a step of differentiation towards the neurosecretory type.

These observations support the view that cells undergo stable modifications in their differentiated properties in the *in vitro* conditions, but retain the ability to express their specific function under favourable conditions such as *in vivo*. It seems unlikely that the changes observed in the populations could be due to selective growth of pre-existing neurophysin cell type, since the F7 cell population inoculated into the animal originated from a single cell progeny, and grows as a stable line. Its growth rate being about four times faster than the neurophysin-vasopressin synthesising cell type, it has a selective advantage in the culture conditions, and would rapidly overgrow a neuronal cell, if any. If F7 cells were able to segregate neurophysin synthesising cells *in vitro*—it could not be observed with our markers—this would argue for F7 being a precursor cell type of a neurophysin cell. Finally inoculation of 10⁷ cells of the neurophysin-vasopressin synthesising C7 clone¹ into syngeneic mice did not give any tumour.

The *de novo* synthesis of a differentiation gene product associated with the *in vivo* passage is a striking phenomenon. Such induced morphological and cell function alterations have been reported in the case of endocrine tumour cells: hormonal activity may be restored in tumour cells which no longer synthesise their specific product, by animal passage³. In the case of teratocarcinoma, lines can be established that remain undifferentiated. Some of these, when injected into mice, give rise to tumours containing various tissues^{4–6}. In our case more studies are needed to determine whether this primitive cell F7 is only a precursor of a neurosecretory cell lineage or is a more remote stem cell for nerve cell types such as glial cells or other types of neurones. But these cells might be used as a suitable model to study the sequence of steps involved in the progressive differentiation of a neuronal lineage.

I thank A. Tixier-Vidal for constant support, Dr E. A. Zimmermann for neurophysin I antiserum and Dr P. Czernichow for neurophysin II and LVP antisera. This work was supported by grants from the CNRS.

Interferon inhibits dimethyl sulphoxide-induced erythroid differentiation of Friend leukaemia cells

INTERFERON (IF), as well as showing antiviral activity is able to inhibit cell growth and metabolism both *in vivo*^{1,2} and *in vitro*^{3–5}. In the *in vitro* systems used, dead cell counts are always very low, indicating that IF inhibits cell growth by decreasing their doubling potential^{4,5} without appreciable cell death. Since we have shown previously that IF inhibits *in vivo* growth of Friend virus (FLV)-induced murine erythroleukaemic cells (FLC)⁶, we have studied the *in vitro* effects of IF addition to cultures of FLC. These cultures, on exposure to dimethyl sulphoxide (DMSO), undergo massive erythroid differentiation accompanied by haemoglobin (Hb) synthesis^{7,8} as a consequence of production of globin messenger RNA^{9,10}. Here we present evidence for a dose-dependent and reversible inhibitory effect of IF on both growth and erythroid differentiation of DMSO-stimulated FLC.

Several preparations of interferon were used in the

Fig. 1 Growth curves of Friend leukaemia cells (FLC) treated with DMSO and/or IF. FLC (clone 745A from C. Friend), grown in suspension cultures in Dulbecco's modified Eagle's medium, supplemented with 15% foetal calf serum and antibiotics, kept at 37 °C, were seeded at 10⁵ cells per ml with no further treatment (○); with 1.5% (by vol.) DMSO (●) and with 1,000 units of IF (■). To samples of 1.5% DMSO-treated cultures, 1,000 U of IF were added either on day zero (▲), or on day 1 (×), or on day 2 (△), or on day 3 (□). Data shown are means $\pm$ s.e.m. of viable (trypan blue dye-exclusion method) cell counts from several experiments. Mouse IF preparations were from Drs I. Gresser and F. Dianzani. Procedures for IF production, partial purification and titration have been described¹⁶.

present study: IF dosages are given in mouse interferon units equal to 4 mouse interferon reference standard units.

IF was initially added at the time of cell seeding (day zero) without DMSO. A pilot experiment showed that IF at 1,000 units per ml per 10^5 cells inhibited FLC growth five-fold with no cell death, as judged by trypan-blue dye exclusion method (Fig. 1, ■). This inhibition was markedly enhanced when IF and DMSO were given simultaneously on day zero. In these conditions, where not even one round of cell doubling occurred and a few dead cells were observed on days 4 and 5, no Hb synthesis was detectable. This is in keeping with reports^{11,12} that at least one cell doubling is required for DMSO induction of Hb synthesis, although this is not necessarily true for other inducers such as butyric acid¹³.

When, instead, IF was added 24 h later (day one) to cultures seeded with DMSO so that the cell population was allowed to undergo at least one doubling before being exposed to IF (Fig. 1, ×), the addition of IF still inhibited cell growth. The IF-treated cultures reached on day 5 a concentration of about 7×10^5 per ml without appreciable mortality. This implies that the cells doubled almost twice after the addition of IF. In these conditions, used in most experiments described hereafter, a ninefold reduction of Hb production, as measured on the fifth day of culture, was observed (Table 1). Hb values of DMSO+IF-treated FLC remained low even when tested on day 7. This effect was much less evident when IF was added on day 2 or 3. On the other hand, there was only a twofold reduction in the accumulation of ⁵⁹Fe and its incorporation into haem.

The IF effects on cell replication and differentiation are dose-dependent (Fig. 2). It is noteworthy that at least 500 units of IF per ml per 10^5 cells are needed to appreciably detect them. This most probably accounts for the apparent discrepancy between our data and those of Swetly and Ostertag¹⁴ and Lieberman *et al.*¹⁵, who found that doses of IF capable of inhibiting FLV production by FLC *in vitro* had no appreciable effect on cell growth and DMSO-induced erythroid differentiation of these cells.

That the observed effects are attributable to IF itself rather than to unknown contaminants of IF preparations is indicated by the following evidence. First, effects induced by IF preparations of various degrees of purification ($\geq 10^6$ units per mg protein for Gresser preparations, 10^5 or 10^4 units per mg protein for Dianzani preparations) are indistinguishable. Second, mouse IF proved equally active regardless of the cell type used as source of IF (brain, fibroblasts, ascites cells) and of the various inducers (West Nile virus or Newcastle disease virus). And third, rabbit heterologous IF or mouse mock IF (medium from uninduced cultures) were ineffective (data not shown).

Inhibition of growth and differentiation of FLC can be fully reversed by thorough washing to remove IF (Table 2). Growth curves of IF-treated cell cultures, following washing

Fig. 2 Dose response curves of IF inhibitory effect on FLC growth and DMSO-induced differentiation. Data are the average of triplicate samples of 5-d cultures seeded with 1.5% DMSO and given the indicated IF amounts on day 1. Benzidine-positive (B+) cells counted on cyto-centrifuge sediments stained with Ralph's technique. At least 500 cells were scored. Viable cell counts as for Fig. 1. Haemoglobin measurements were carried out on cell lysates as described for Table 1. ●, No. of cells per ml. □, % B+ cells. ○, $\mu\text{g Hb per } 10^7 \text{ cells}$.

and reseeded at 10^5 cells per ml are indistinguishable from controls, when checked daily. Similarly, reversal of the inhibition of erythroid differentiation has been accomplished. As shown in Table 2, when cells induced with DMSO and treated with IF under the usual conditions were washed and reseeded at high and low density in fresh DMSO- and IF-free medium, amounts of Hb detected in cells that had or had not been treated with IF were comparable. When, however, cells obtained at the fifth day of culture after DMSO+IF treatment, were washed and reseeded into DMSO-supplemented medium, they were fully reinducible by DMSO indicating that IF treatment had not merely selected a DMSO-resistant variant.

Thus our results suggest a marked inhibitory capacity of IF on DMSO-induced Hb production by FLC. It should be emphasised that the decrease of Hb synthesis occurs in conditions where the overall protein synthesis is not affected by IF treatment. This was determined by measuring acid-precipitable radioactivity after pulses or continuous labelling with ³H-arginine (data not shown). The IF-induced inhibition of Hb synthesis is reversed by removal of IF, further

Table 1 Effect of IF on ⁵⁹Fe accumulation, its incorporation into haem and Hb production of FLC cultures

Treatment	⁵⁹ Fe accumulated (c.p.m. per 10^7 cells)	⁵⁹ Fe incorporated into haem (c.p.m. per 10^7 cells)	Hb ($\mu\text{g per } 10^7 \text{ cells}$)
None	13,251	1,421	4.76
DMSO 1.5%	38,402	3,632	47.46
DMSO + IF on day 1	19,922	1,872	5.52
DMSO + IF on day 2	36,435	4,505	29.30
DMSO + IF on day 3	39,649	4,389	25.24

Data shown are for samples obtained at day 5 for culture from a representative experiment. FLC cells were seeded at the density of 10^5 per ml with or without 1.5% DMSO in presence of $0.1 \mu\text{Ci ml}^{-1}$ ⁵⁹Fe-citrate. 1,000 units of IF were added to separate culture samples at time intervals indicated. On day 5, cells were washed, resuspended in 3.0 ml distilled water, and lysed by repeated freeze-thawings. Aliquots of lysates were counted for radioactivity (⁵⁹Fe accumulated). Haem was extracted from lysates according to Scher *et al.*¹⁷ and the radioactivity of such extracts counted (⁵⁹Fe incorporated). Haemoglobin was measured from cell lysates according to Crosby and Furth¹⁸.

Culture conditions as for Fig. 1. 1,000 Units of IF added on day 1. Haemoglobin measured according to ref. 18.

*Tested 48 h after treatment.

†Tested 96 h after treatment.

confirming the specific character of its effect. The prompt resumption of Hb production in absence of DMSO after IF removal suggests that IF action had not effaced the DMSO imprinting of FLC.

Work is in progress to determine, at the molecular level, the mechanism by which IF addition inhibits Hb synthesis. It is apparent, however, that globin synthesis or its assembly into Hb rather than haem production is the most likely target of IF action.

We are thankful to Drs I. Gresser and F. Dianzani for generous gifts of IF and continuous encouragement, to Drs C. Friend and A. Fantoni for helpful suggestions and for reading this manuscript, and to Mr P. Di Chiara for excellent technical assistance. This work was supported in part by grants from NATO, Consiglio Nazionale delle Ricerche and Fondazione Anna Villa Rusconi.

Polyclonal Ig production after Epstein-Barr virus infection of human lymphocytes *in vitro*

APART from the specific anti-Epstein-Barr virus (EBV) response in infectious mononucleosis (IM), there is a strong general increase of antibody levels¹. The major increase comprises IgM. As EBV has been shown to infect B lymphocytes selectively² we hypothesised that the virus triggered the infected cells to release immunoglobulin, much like the effect of certain B-cell mitogens³, although the mechanism of activation must be different. It is known that EBV infection *in vitro* of human blood lymphocytes gives rise to increased DNA synthesis⁴ and that lymphoid cell lines carrying the EBV genome shed or release immunoglobulins⁵ of various classes. Furthermore, the IgM increase seen in IM would fit with a polyclonal B-cell activation (PBA) of EBV as PBA usually gives rise to IgM secretion⁶. To test this hypothesis, we have exposed lymphocytes from cord blood and adult peripheral blood to EBV *in vitro* and measured the released IgM, by a double-antibody radioimmunoassay, and individual antibody-forming cells (PFC) against haptenated red blood cells and sheep red blood cells (SRBC).

Lymphocytes, both from EBV seronegative and EBV seropositive donors were infected with strain B95-8 of EBV. Table 1 shows that DNA synthesis, as measured by ³H-thymidine incorporation, increased considerably over the non-infected control cultures, which, however, were stimulated to some degree by the foetal calf serum (FCS) in the medium. The stimulation ratios between infected and control cultures varied from 1.5 to 20 and there was no obvious difference between lymphocytes from cord blood and adults. The amplitude of activation seemed to be specific to each donor, with no correlation with the origin of the lymphocytes. We wished to know whether the B lymphocytes were triggered to become Ig-producing cells, because these infections mimic the *in vivo* situation found in IM. IgM was present from day 3 after infection, as measured by radioimmunoassay, and increased in most cultures by a factor of 10 until day 7 (Table 1). Lymphocytes from adult EBV positive donors secreted detectable IgM in control cultures (Table 1) but at a significantly lower level than in virus-stimulated cultures. The double-antibody radioimmunoassay for IgM was specific for human IgM, and no interference with other human proteins or FCS proteins was observed.

To confirm the radioimmunoassay results, we collected spent media from infected and control cultures and labelled them with ¹²⁵I. Monospecific antibodies against μ , γ , κ and λ chains were used to precipitate out Ig from the bulk of other proteins in the spent medium. The results indicate (Table 2) that the Ig produced is polyclonal, because all

*Sensitivity of radioimmunoassay: 3 ng ml⁻¹. ND, not done.

†Values from infected cultures; control cultures were always negative.

Lymphocytes were separated on Ficoll-Isopaque¹⁷. Two batches of EBV (supernatant of B 95-8 cells (ref. 7) filtered through a Millipore membrane pore size 0.45 µm) were used. Lymphocytes were pelleted and resuspended in B 95-8 supernatant (1 ml was added to 10⁶ cells). The cells were incubated for 1 h at 37 °C with continuous shaking. Thereafter the cells were washed three times with medium (RPMI 1640, supplemented with 10% FCS and antibiotics), finally they were resuspended in medium to a concentration of 10⁶ cells per ml. Cells were incubated for 7 d at 37 °C in 5% CO₂ and 95% air in 50-ml plastic bottles (Falcon plastics). 16 h before collection 10⁶ cells were transferred into Falcon microplate wells (2 × 10⁵ cells in each well) and 1 µCi ³H-thymidine (Amersham, specific activity: 5 Ci mmol⁻¹) was added to each well. The cultures were sucked off with the aid of multiple sample processor (Skatron, Norway) to glass fibre filters. After drying, the filters were placed in vials containing scintillation fluid. The isotope determinations were made by a Packard Tri-Carb scintillation spectrometer and expressed as c.p.m. EBV-determined nuclear antigen (EBNA) staining was carried out on day 7 according to the method of Reedman and Klein¹⁸. A double-antibody radioimmunoassay was established for measurements of minute amounts of IgM. IgM was isolated from a pool of human serum by precipitation with 50% saturated ammonium sulphate, washed three times with 33% saturated ammonium sulphate, dialysed against 0.1 M Tris-HCl buffer, pH 7.4, containing 1 M NaCl and fractionated on Sephadex G-200 in the same buffer. The first peak was pooled and fractionated by Pevicon block electrophoresis in Veronal-HCl buffer, pH 8.6, $I=0.1$. Isolated IgM was kept in a 0.1% glycine buffer in phosphate buffered saline, pH 7.4, to avoid aggregation. The purified IgM was labelled with ¹²⁵I according to a modification to Hunter and Greenwood¹⁹. Radioimmunoassay was performed as follows: 10 µl spent medium or standard (purified IgM) in twofold dilutions from 25 to 0.05 ng was incubated for 4 h, 37 °C with 10 µl of rabbit anti-IgM (Dakopatts, Copenhagen), diluted 1:4,000 plus 25 µl of normal rabbit serum diluted 1:500. Then 10 µl of labelled purified IgM (0.5 ng labelled with 5,000–10,000 c.p.m.) added and the mixture incubated for 1.5 h at 37 °C. 25 µl of sheep anti-rabbit globulin 1:50, was then added for 18 h of incubation at 4 °C. All reagents were diluted in a 10 mM Tris-HCl buffer, pH 7.5, containing 1 mM EDTA, 15 mM NaCl and 0.4% Triton X-100 and 20 mg bovine serum albumin (BSA) per ml. Precipitates were washed three times in cold buffer without detergent and BSA and counted in an Intertechnique γ-counter. A standard curve was plotted and the concentration of IgM of the unknown samples from the spent medium of infected and non-infected cultures were determined according to the standard curve. A similar radioimmunoassay for Ig light chains has recently been described by Rosén *et al*²⁰.

four antisera showed significant precipitation values. Autoradiographic analysis of the radioactive precipitates on slab gels (4–25% gradient sodium dodecyl sulphate-polyacrylamide gel, in non-reducing conditions) confirmed two facts: 19S IgM was synthesised and both IgG and IgM were produced by the stimulated cells (unpublished results of A. R. and R. Laskov). The control culture precipitates showed weak bands in the positions of IgM and IgG but the quantitative differences were striking.

We have looked for several antibody specificities, including the heterophile antibody in the immunoglobulins from the supernatants of the EBV-stimulated cultures, but without success. However, when testing for single antibody forming cells (Table 3) in a modified plaque assay* after 6 d of culture, we found that EBV-exposed cord blood lymphocytes generated direct PFC against both haptenated RBC and SRBC. The frequencies were of the same order as with cells exposed to 20 µg of pokeweed mitogen. Single antibody-forming cells were developed following the principles described by Jerne and Nordin²¹, but essentially with the modifications for human effector cells described by Fauci and Pratt²². Purified blood lymphocytes (5 × 10⁶) were spun down and incubated in 1 ml of supernatant of B 95-8 for 60 min at 37 °C. After two washes the cells were incubated

in flasks (Falcon 3013) at 10⁶ per ml in RPMI in 10% FCS and 5% CO₂ in air. After 3–7 d the cells were collected and plaqued on thin-layer agarose as described by Bullock and Möller¹⁰. The target cells were SRBC or haptenated (FITC) SRBC (ref. 11). Only direct PFC were studied. Guinea pig serum diluted 1:40 was the source of complement. As a B-cell mitogen, 20 µg of pokeweed mitogen was added to 5 × 10⁶ lymphocytes for the whole culture period.

Between 50 and 90% inhibition of the number of plaques formed was observed when a rabbit anti-IgM antiserum was added before plaques were developed. This indicated that IgM antibodies caused plaque formation.

EBV nuclear antigen (EBNA) (ref. 18) was induced as a result of infection (Table 1). The appearance of EBNA agrees with the assumption that the stimulation of B cells was due to the penetration of EBV into the cells.

We have demonstrated that peripheral blood lymphocytes from cord blood and adults make immunoglobulins after exposure to EBV *in vitro*. The impact of this finding is threefold. First, we believe that it represents an *in vitro* correlate of the *in vivo* infection with EBV in IM¹² because there is an increase of polyclonal IgM in this disease¹. Our demonstration of IgM and IgG with κ and λ chains by immunoprecipitation and single PFC with at least two antibody specificities (anti-FITC and anti-heterologous RBC) suggests polyclonality of these antibodies induced *in vitro*. Ig secretion has been reported², by established lymphoid lines made immortal by the addition of EBV¹³. This study, however, reveals the early events, before the establishment of a line.

Our data show that human newborn and adult peripheral blood contains cells that can be induced to produce antibodies. Antibody-producing potential is thus not confined to stationary cells of lymphoid organs, and age does not seem to influence this capacity at least with regard to IgM

Table 2 Precipitation of Ig from ¹²⁵I-labelled supernatants

Antibody	Donor 1	% Precipitated*	Donor 2
Anti-μ chain	1.0		1.0
Anti-γ chain	0.8		1.2
Anti-κ chain	0.3		0.3
Anti-λ chain	0.4		0.3

The precipitation systems were optimised by titrating purified IgM or IgG against 50 µl of the rabbit antisera.

*Infected minus control.

Plaque assay was done after 6 d culture, both against FITC-coupled sheep red blood cells (FITC-SRBC-PFC) and SRBC alone (SRBC-PFC).
 *A 1-ml sample of EBV from B 95-8 supernatant was added to 5×10^6 in 2 ml of purified blood cells from umbilical cord and adult donors. of unknown immune status to EBV. The mixture was incubated for 1 h at 37 °C and the cells were washed and cultured.

†20 µg pokeweed mitogen was added at start of culture.

antibodies. Finally, we believe that EBV activation will be helpful in the study of B-cell triggering as the virus binds to B lymphocytes by means of receptors that are intimately associated with the complement receptors¹⁴. There is still controversy^{15,16} as to whether mere binding to the complement receptor will result in full activation of the B lymphocytes. We intend to explore this area, utilising the same experimental system, by exposing blood B lymphocytes to both non-transforming and heat inactivated EBV, respectively, both of which supposedly bind to B lymphocytes by means of the same receptor as normal EBV. We also plan to investigate whether the antibody-forming cell is EBNA positive in these conditions and, if so, whether an EBNA positive B cell can make anti-EBV antibodies.

Prevention of oncornavirus-induced sarcomas in cats by treatment with antiviral antibodies

In mice, infections with leukaemogenic viruses, as well as subsequent development of disease, can be permanently suppressed by treatment with antibodies specific for the major glycoprotein (gp71) of Friend murine leukaemia virus (MuLV Friend)^{1,2}. Similar protocols using antibodies

to feline leukaemia virus (FeLV) result in elimination of FeLV infection in 6-month-old kittens. Furthermore, FeLV-infected kittens became non-viremic after treatment with antibodies to the murine virion glycoprotein³. This finding indicates that the interspecies portions of C-type virus glycoproteins can be suitable targets for immunotherapeutic regimens. It was of interest to extend the studies with leukaemia viruses to agents which induce other classes of neoplasms. We describe here a study of the effect of antibody therapy on infections in cats with feline sarcoma virus (FeSV). Our preliminary results indicate that antibody therapy can be effectively applied for prevention of virus-induced solid tumours. Moreover, this tumour model may be more attractive and amenable to study than virus-induced leukaemia.

The virus used in these studies was the Snyder-Theilen strain of FeSV. Kittens were injected with aliquots from a single pool of cell-free tumour extracts containing between $10^{3.2}$ and $10^{4.2}$ focus inducing units (FIU) representing about 10^3 and 10^4 cat LD₅₀ units respectively.

The antisera used have been described in detail elsewhere^{2,3}. Briefly, goat antiserum to FeLV ('FeLV serum') neutralised the homologous virus to a high titre (1/8,000) and was highly cytotoxic in a Cr-release test for FeLV producing F422 cells (titre 1/8,000). This serum was absorbed with foetal calf serum and normal cat antigens before use. Goat antiserum to MuLV Friend gp71 ('MuLV gp71 serum'), also prepared in goats, neutralised FeLV to a titre of 1/400 and was cytotoxic for F422 cells to a titre of 1/500. Total globulins of both sera were obtained by precipitation with ammonium sulphate. The IgG fraction of MULV gp71 serum was then isolated by chromatography on DE-52. The respective globulin fractions and MuLV gp71 IgG were used at a concentration of $5 \times$ with respect to whole serum volume.

Three-week-old kittens from a specific pathogen-free colony were infected subcutaneously (s.c.) in the scapular region with the cell-free FeSV tumour extract. Six or 12 d later, whole serum, globulins or IgG were administered once intraperitoneally followed by seven s.c. injections over a period of 16 d (see Table 1). In Experiment I, all kittens were from the same mother, whereas the other studies were with randomised animals.

As can be seen from the effect on the 11 control animals, represented by untreated animals or groups which received normal goat serum globulins, the FeSV tumour extract was lethally oncogenic in our system. All animals died after development of progressive sarcomas with many secondary growths which probably, in large measure, represent new primaries induced by FeSV. The mean survival period for kittens infected with $10^{3.2}$ FIU was 53 ± 9.4 d, whereas the animals receiving the higher virus dose died somewhat earlier.

Of the two antibody treatments employed, the outcome with FeLV-serum globulins was more effective. When the

‡ This animal died of enteritis; no tumour evident.

treatment was initiated 6 d post-infection (p.i.), none of the animals died as a consequence of tumour development. The single animal in Experiment I which died 90 d p.i. was lost due to enteritis, and showed no evidence of tumour. In Experiment III, where only one kitten was tested, no tumour developed even when the antibody treatment was initiated as late as 12 d p.i.

Kittens in Experiment I, receiving the higher virus dose, developed clearly palpable tumours at the site of FeSV inoculation during antibody treatment. In contrast to the situation in the control animals these tumours completely regressed. After antibody treatment, scars remained in the skin at the site of virus inoculation which were surrounded by pigment-free hairs (Fig. 1b). This occurred regardless of whether palpable tumours were detected. Thus far, no indication has been obtained that any of the surviving animals have developed new tumours (in Experiment I this represents nearly 285 d p.i.).

Some protection against FeSV tumour development was also achieved with the MuLV gp71-IgG, although in this study (Experiment IV), only two of five kittens survived. One of the surviving animals developed a visible tumour which subsequently regressed. Thus, interspecies MULV gp71 antibody can be effective against solid tumours induced by FeSV. Additional studies using larger amounts of IgG and other protocols are in progress to improve the effect of the treatment.

Our previous studies in kittens cured of FeLV infection by antibody treatment revealed that the non-viremic animals resisted subsequent challenges with FeLV and developed significant neutralising titres against the virus³. Some of these animals received three further challenges with live FeLV and one with FeSV. One female cat from this group of hyperimmunised animals was mated and subsequently delivered three kittens which were challenged with $2 \times 10^{3.2}$ FIU of FeSV tumour extract at 22 d of age. These animals had not developed any palpable tumours at 70 d p.i.

The prime features of these preliminary studies can be

Fig. 1 a, Tumour of a control cat infected with $10^{3.2}$ FIU of feline sarcoma virus: 60 d p.i. b, Scar of a cat infected with $10^{3.2}$ FIU and treated with FeLV serum globulin: 43 d p.i.

summarised as follows: (1) Protection against death from development of progressive FeSV-induced tumours can be achieved by administration of globulin fractions from goats immunised with (a) FeLV and (b) MuLV gp71. (2) In some cases, animals protected by the antibody treatment developed sizeable tumours at the site of virus inoculation. But, these tumours regressed while control cats died of progressive sarcomas. (3) Scar formation at the site of FeSV inoculation was observed in several cases in recovered animals. (4) Preliminary results indicate that transfer of immunity from mother to offspring may be possible.

The system described above seems to represent a classical model for study of tumour growth and regression in the cat in response to external immunological controls. It is certainly remarkable that by simple application of antibody, it is possible to achieve such a striking effect on a solid tumour without any obvious detriment to the host. Of particular interest are the cases where the tumour was detectable by palpation during the course of antibody treatment, suggesting that a direct interaction of the heterologous antibody with the growing tumour may occur. The actual mechanism by which the tumour is eliminated and the significance of the residual scars are under investigation. Our previous experience in the mouse and cat indicates that an immune response by the host was required for long-term protection against virus infection and/or leukaemia development. In the present system, such an immune response could be directed against prominent cell surface antigens including virus structural components and/or FOCMA (ref. 4). Further studies are required to determine if such host immunity is in fact activated, and whether it is sufficient to guarantee long-term protection against sarcoma. The transfer of immunity from mother to offspring reported also by others in the cat^{5,6} as well as in the mouse^{7,8} is an important phenomenon. The nature and specificity of the antibodies primarily involved, however, are not yet known.

The results presented above together with other studies in the mouse and cat are highly promising and suggest possible application of antibody therapy to other virus-induced malignancies. Of special interest in this regard is the interspecies activity of the antibody *in vivo*. This raises the possibility that tumours in widely differing species expressing cross-reactive glycoprotein antigens will be amenable to similar studies, using well-characterised reagents such as anti-MuLV gp71 antisera.

This work was supported by the American Cancer Society and the NCI. We thank A. Poco for technical assistance and Drs H. Schwarz and J. Thiel for preparing MuLV antibodies.

Melanotropin-daunomycin conjugate shows receptor-mediated cytotoxicity in cultured murine melanoma cells

MELANOTROPIN (MSH) binds to specific receptors at the surface of mouse melanoma cells, preferentially in the G-2 phase of the cell cycle¹. On prolonged incubation, a fluorescein-MSH conjugate is internalised and appears intracellularly in small vesicles². The same phenomenon has been demonstrated by electron microscopy with an MSH-ferritin-fluorescein conjugate³. Although a role for the internalisation of MSH receptors in the execution of the hormonal message is still open to question, the fact that these conjugates of MSH are specifically recognised and internalised by melanoma cells offers a possibility for specific, site-directed chemotherapy of melanomas. We have therefore assumed that MSH-toxin conjugates might be specifically recognised and internalised and thereby have a selective toxic effect on cells that display MSH receptors on their surface. Even though the principle of site-directed chemotherapy has been known for a long time, it is only recently that this field became active⁴. Conjugates of specific antibodies and cytotoxic substances⁵⁻⁷, as well as a DNA-daunomycin complex⁸ have been used in an attempt to increase the selectivity of the toxic agents. In this report we describe the synthesis of a melanotropin-daunomycin conjugate and its MSH receptor mediated cytotoxic effect on mouse melanoma cells *in vitro*.

A melanotropin-daunomycin conjugate was prepared using the procedure developed by Hurwitz *et al.*⁹ for the covalent binding of daunomycin to antibodies. Daunomycin 20 mg (380 μ mol) (Sigma) was dissolved in 1.5 ml phosphate-buffered saline, pH 7.4 (PBS). NaIO₄ 11.5 mg (540 μ mol) was added and the mixture was incubated at 22 °C in the dark for 1 h. The excess NaIO₄ was neutralised with glycerol, added to a 50 mM final concentration. 30 mg β -MSH (prepared by us¹⁰) containing 1 μ Ci of ¹²⁵I-MSH (1) as a marker was added in 1 ml of 0.15 M K₂CO₃ (pH 9.5). The mixture was incubated for 1 h at 22 °C. The resultant conjugate was reduced by NaBH₄ (0.3 mg ml⁻¹) at 37 °C for 2 h. The reaction mixture was applied to a Sephadex G-25 (90 cm $\times$ 2 cm) column and eluted with PBS. Radioactivity of the fractions was measured by a γ -counter and the concentration of daunomycin was monitored spectrophotomerically at 495 nm. The appearance of the red colour in the void volume, coincident with the major peak of ¹²⁵I-MSH indicated the presence of a melanotropin-daunomycin conjugate (Fig. 1). On the basis of

Fig. 1 Separation of melanotropin-daunomycin on Sephadex G-25. A reaction mixture of melanotropin-daunomycin was applied to a Sephadex G-25 column as described in the text. Radioactivity (●) and absorbancy at 495 nm (○) of the fractions is shown.

the specific radioactivity and absorbancy at 495 nm of the major fraction, the molar ratio of daunomycin to MSH in the conjugate was calculated to be 2.2:1. The purity of the compound was tested by high voltage electrophoresis. The purified conjugate was hydrolysed by 6 N HCl at 110 °C for 18 h and the amino acid composition was determined, parallel with the hydrolysate of a mixture of daunomycin and unconjugated β -MSH. About 50% of lysine and aspartic acid were recovered from the conjugate indicating that the oxidised product of daunomycin (D) had substituted the ϵ -aminolysyl residue(s) (no. 6 and/or no. 17) and the terminal amino group of aspartic acid. This suggests the following general formula for the melanotropin–daunomycin conjugate:

Efforts to delineate substitution of lysyl residues by analysis of tryptic and chymotryptic hydrolysates were unsuccessful.

The cytotoxic index of daunomycin was 0.99 when the antibiotic was added in 4 μM concentration to cultures of melanoma cells. Melanotropin-daunomycin showed the same level of toxicity at 1.4 mM (Table 1). On a molar basis, therefore, the daunomycin-MSH conjugate is about three times more toxic to melanoma cells than free daunomycin. MSH, daunomycin and melanotropin-daunomycin conjugate markedly changed the morphology of melanoma cells. With daunomycin, cells develop large nuclei, most probably due to a G-2 block, similar to that observed in other systems¹¹; surviving cells showed no dendritic processes. In the presence of melanotropin-daunomycin, mostly cells with large nuclei were found with normal or fragmented processes. The median cell volume in the control cultures was 1,450 μm^3 ; in the presence of MSH 1,500–2,000 μm^3 ; and with melanotropin-daunomycin, 1,700–2,600 μm^3 . Although free daunomycin was as toxic to 3T3 cells as to melanoma cells, melanotropin-daunomycin (1.4 μM) was not toxic to 3T3 fibroblasts (Table 1). Neither MSH (0.2 mM)

nor MSH–daunomycin (1.4 μ M) had significant effect on the morphology or size of 3T3 cells. The toxic effect of melanotropin–daunomycin can be prevented by free MSH; free MSH has no effect on the toxicity of daunomycin (Table 1).

Daunomycin or melanotropin–daunomycin conjugate was added to coverslip cultures of melanoma cells and of 3T3 cells and the uptake of daunomycin was monitored by fluorescence microscopy. After 1 h of incubation at 37°C, internalisation of daunomycin was detected by fluorescence microscopy with both melanoma and 3T3 cells (Fig. 2*a,b*). The daunomycin–melanotropin complex was internalised by melanoma cells only (Fig. 2*c,d*) and this process could be blocked by free melanotropin (Fig. 2*e*). Melanotropin had no effect on the uptake of daunomycin by melanoma cells (Fig. 2*f*) or by 3T3 cells (not shown).

Thus we have synthesised a melanotropin–daunomycin conjugate which is more toxic to mouse melanoma cells than daunomycin alone and in the same concentration range the conjugate is not toxic to mouse 3T3 fibroblasts. This increase in selective toxicity is remarkable because unconjugated daunomycin is equally toxic to both cell lines (Table 1); the same cytotoxicity of free daunomycin was found in other systems^{8,9}. Because both the toxic effect and uptake of melanotropin–daunomycin in melanoma cells can be partially prevented by free melanotropin (Table 1 and Fig. 2), we assume that recognition of melanotropin–daunomycin by MSH receptors, present on melanoma cells¹ but absent from 3T3 cells (unpublished work), is responsible for the enhanced selective toxicity.

As we could demonstrate by fluorescence microscopy, after 1 h of incubation, the fluorescence of unconjugated daunomycin (or the fluorescence of the aglycone) appears in the nuclei of both melanoma and 3T3 cells.

In contrast, melanotropin–daunomycin appears in melanoma cells only. Whether the conjugate reaches the nucleus intact or whether it is degraded, is not known. The mechanism of penetration of melanotropin–daunomycin into melanoma cells is probably similar to the endocytosis we observed with fluorescein–MSH (ref. 2) and with fluorescein–ferritin–MSH (ref. 3). These conjugates as well as ^{125}I –MSH (ref. 12) bind in patches on the surface of melanoma cells at 0 °C (refs. 2, 3, 12). At 37 °C, FITC–MSH appear in vesicles² and the MSH–ferritin–FITC conjugate in premelanosomes in a few hours. We assume that endocytosis of these conjugates resembles phagocytosis by

Table 1 Toxicity of melanotropin-daunomycin on melanoma and 3T3 cells

Cells	Additions to culture medium	Cytotoxic index*
Melanoma	None	0.00
	Daunomycin, 4 μ M†	0.99
	Daunomycin, 4 μ M + melanotropin, 200 μ M	1.00
	Melanotropin, 2 μ M	0.05
	Melanotropin–daunomycin, 0.35 μ M	0.65
	Melanotropin–daunomycin, 0.70 μ M	0.87
	Melanotropin–daunomycin, 1.40 μ M	0.98
	Melanotropin–daunomycin, 1.40 μ M + melanotropin, 4 μ M	0.57
	Melanotropin–daunomycin, 1.40 μ M + melanotropin, 40 μ M	0.47
3T3	Melanotropin–daunomycin, 1.40 μ M + melanotropin, 200 μ M	0.28
	None	0.00
	Daunomycin, 4 μ M†	0.99
	Melanotropin, 2 μ M	0.01
	Melanotropin–daunomycin, 1.4 μ M	0.02

Cloudman S-91 melanoma cells (NCTC 3960) were inoculated in 25 ml Falcon flasks and cultivated at 37 °C in an atmosphere containing 5% CO₂, in Ham's F-10 medium supplemented with 5% foetal calf serum and 2 U ml⁻¹ gentamycin. The mouse 3T3 fibroblast cell line (from Dr Paul Lebowitz) was cultivated in Earle's MEM containing 5% foetal calf serum, 100 U ml⁻¹ penicillin and 100 U ml⁻¹ streptomycin. After 1 d of growth, the medium was changed to a fresh one containing additions as listed. After 3 d in culture, the cells were rinsed with fresh medium and removed from the flasks by shaking, after treatment with EDTA in Tyrodes solution¹. The cells were pelleted by centrifugation (1,000*g*, 5 min.) and washed with serum-free medium. The number and size of the cells was determined with a Coulter 'channelyser'. Cell viability was determined by a modification of the dye exclusion test¹⁴. Four parallel flasks were used for each point.

$$\text{*Cytotoxic index} = \frac{(\text{no. viable cells in control culture} - \text{no. viable cells in treated culture})}{(\text{no. viable cells in control culture})}$$

†Minimum dose of daunomycin required for maximum cytotoxicity. This was determined from dose-response curves and the values for melanoma and 3T3 cells were similar to those observed with other cell types^{8,9}.

Fig. 2 Fluorescence microscopy of daunomycin and melanotropin-daunomycin treated cells. Melanoma cells and 3T3 fibroblasts were grown for 2 d in Ham's F-10 medium on coverslips. Before treatment, the cultures were rinsed with fresh medium; then incubated at 37 °C for 60 min as follows: *a*, melanoma cells were incubated with 4 μM daunomycin; *b*, 3T3 cells with 4 μM daunomycin; *c*, melanoma cells with 1.4 μM melanotropin-daunomycin; *d*, 3T3 cells with 1.4 μM melanotropin-daunomycin; *e*, melanoma cells with 1.4 μM melanotropin-daunomycin + 0.1 mM melanotropin; *f*, melanoma cells with 4 μM daunomycin + 0.1 mM melanotropin. After incubation, cells were rinsed with serum-free medium (0 °C), fixed with 2% paraformaldehyde for 5 min (0 °C), rinsed with distilled water and air-dried. Preparations were mounted with Leitz immersion oil and cellular localisation of the red fluorescence (white areas on the microphotographs) due to the presence of free daunomycin or melanotropin-daunomycin was detected by fluorescence microscopy by using a Leitz Diavert microscope equipped with a 100 W mercury burner and a Ploem epi-illuminator.

macrophages¹³ suggesting that MSH receptors may play a similar role on melanoma cells as Fc receptors do on macrophages: the formation of a ligand receptor complex may signal endocytosis. Accordingly, the absence of MSH receptors and permeability barrier to MSH in 3T3 cells would explain lack of endocytosis of the hormone-toxin conjugate which may be responsible for the resistance of 3T3 cells to melanotropin-daunomycin.

We thank Dr Alan Sartorelli for critically reading the manuscript. This work was supported by grants from the USPHS and the American Cancer Society.

Procarcinogen activation and hormonal control of cell proliferation in differentiated primary adult rat liver cell cultures

CONCERTED interactions among hormones and nutrients control animal cell proliferation¹. For example, in the rat, insulin, glucagon, glucocorticoid, parathyroid hormone, iodothyronines and amino acids regulate normal hepatic proliferation—a prominent system for studying epithelial cell growth control². Endocrine and nutritional factors also modify the efficiency with which chemicals produce experimental tumours in these animals notably, the induction of hepatomas by aromatic amines³. We report here observations with a novel primary monolayer adult rat liver culture system which may prove helpful towards studying these interactions under defined conditions⁴. These cells proliferate in response to hormones and nutrients; they maintain differentiated hepatic functions such as albumin and arginine biosynthesis for at least 8-10 days after plating; and they metabolise the procarcinogen *N*-2-acetylaminofluorene (AAF) into a proximate form, *N*-hydroxy-AAF (ref. 5).

Cell isolation procedures and plating methods (which use arginine-free medium to select for arginine-synthesising hepatocytes⁶) are given in Fig. 1 (legend). About 10% of the cells in 5-7 g of normal liver are recovered for plating. Over 95% of these cells are viable (measured by trypan-blue exclusion) and hepatocyte-like with respect to size ($\geq 25 \mu\text{m}$ diameter, measured with an electronic particle counter), to histochemical staining properties (positive for glycogen and glucose-6 phosphatase), and to ultrastructure visualised by electron microscopy (glycogen granules, microbodies, rough endoplasmic reticulum; K. Dempo *et al.*, in preparation). Similar characteristics are retained 24-48 h post-plating by the surviving cell fraction, attached to the plastic substratum, which represents about 10-20% of the initial inoculum and which begins to form monolayer aggregates⁶ at this time (see ref. 4 for photomicrographs). The recovery efficiency⁶ of 10-20% is invariant with inoculum concentrations of 10^5 - 10^6 cells per dish. Cell survival after 72-96 h requires serum (Fig. 1a) without which cells randomly detach (floating cells are dead and eventually most lyse).

Growth curves are shown in Fig. 1. Serum alone fails to sustain significant proliferation rates but if hormones and inosine⁷ are added, especially hydrocortisone or insulin, proliferation is stimulated (Fig. 1a). Titration studies suggest synergistic hormone interactions; stimulation is detected at concentrations as low as 50 ng ml^{-1} . Analogues with negligible potency (for example desAla, desAsp-insulin⁸ or androstenedione⁹) are non-stimulatory. Net increased proliferation, which absolutely requires exogenous ornithine, is otherwise satisfied by 0.4 mM arginine but not by either exogenous putrescine (0.008-0.4 mM) or 8 μM arginine (Fig. 1b). DNA synthesis rate and mitotic kinetic patterns are similar to those reported for foetal hepatocytes¹⁰. Under optimal conditions (Fig. 1a), adult log-phase cultures (96-120 h post-plating) contain at least $46 \pm 2\%$ (s.e.m.; $N = 3$) of cells in S-phase, measured radioautographically¹⁰ following a 16-h pulse with ³H-dT or as estimated by flow microfluorimetric methods⁷.

Similar growth curves are obtained if 24 h cultures receive fresh 24 h cell-free 'conditioned medium'; therefore, enhanced attachment or cell-settling do not cause increased cell numbers.

Serum contains additional stimulatory material for if slowly growing cultures are established in 'complete medium' with 1% serum, then increasing amounts of serum added 24–48 h post-plating produce a dose-dependent family of increasing growth curves (not shown). Triiodothyronine or glucagon (Fig. 1a), and FGF (ref. 11), or EGF (ref. 12) (0.01–1.0 μg ml⁻¹) do not stimulate growth and thus do not seem to be limiting under these conditions (see discussion in ref. 13). Although cell proliferation in this adult system is more dependent than a similar foetal system upon exogenous ornithine¹⁴ and hydrocortisone¹, it is not yet clear if this results from different intrinsic cellular properties and/or from different initial physiological states.

³H-ornithine is a useful probe of specific and general metabolic functions in liver cell cultures⁶ (Fig. 2). These studies indicate that cultured adult cells synthesise albumin and arginine because first, ³H-ornithine enters albumin and cellular macromolecules which, after acid hydrolysis, contain >80% of the protein-associated radioactivity in the form of ³H-arginine (not shown), and second, incorporation is inhibited ≥98% by cycloheximide (5 μg ml⁻¹; not shown). The immunoprecipitation procedure used¹⁵ to measure albumin biosynthesis accurately reflects relative rate differences of albumin production because an independent previously validated radioimmunoassay¹⁵ gives similar results to those shown in Fig. 2. Thus, day 2 and 8 rates measured by radioimmunoassay are 110 and

Fig. 1 Hormonal control of cell proliferation in adult liver cell cultures. Fisher/344 male or female rats (150–200 g) were ether anaesthetised at 0900–1200 h. An abdominal incision was made extending into the thoracic cavity; the rat was exsanguinated by cardiac puncture and its intestinal contents resected. A 20 ml plastic syringe equipped with a 25 gauge × 1 inch needle was inserted into the portal vein, clamped distally to splanchnic and gastric veins, and the superior vena cava was cut. The liver was perfused 2–3 min with 20 ml 'digestion buffer.' This solution contains (in g l⁻¹) Type I Sigma collagenase, 3.0; NaCl, 7.597; KCl, 0.224; NaH₂PO₄·H₂O, 0.138; D-glucose, 1.802; phenol red, 0.0012; insulin (from W. Bromer, Eli Lilly), 0.01; and hydrocortisone-succinate and inosine (Sigma), 0.01 each; it is prepared fresh, adjusted to pH 7.4, sterilised with a 0.45 μm Nalgene filter, and preincubated 1–4 h at 37 °C. Two perfused excised livers were freed of extraneous tissue and washed twice with 10 ml 'complete medium' (arginine-free Dulbecco-Vogt's modified Eagle's medium, supplemented with 0.4 mM L-ornithine, 15% v/v heat inactivated dialysed foetal bovine serum⁶ and 10 μg ml⁻¹ each of glucagon, T₃ and of hormones and purine present in digestion buffer). 'Basal medium' is complete medium minus hormone and purine supplements. Tissue was dissected into 5 × 8 mm pieces, washed twice, pooled and incubated at 37 °C with 40 ml aliquots of digestion buffer in a 125 ml Erlenmeyer flask (four 10-min treatments; 5 cm × 7 mm magnetic stirring bar and Magne-Stir Model No. 10 stirrer, rheostat control 35–40). Cell suspensions after each treatment were transferred to a collecting flask containing 10 ml 'complete medium' at 0–4 °C. Ice-cold medium (160 ml) was mixed into the final pooled cell suspension; 40 ml aliquots were dispersed into eight 50 ml tubes (Falcon) and centrifuged at 150–200g for 13 s. Pellets were gently resuspended in serum-free 'complete medium' and recentrifuged. Resulting pellets were vigorously resuspended and titrated with a Coulter counter (threshold > 10 μm; attenuation, 1; aperture, 256). A third centrifugation step was repeated and the final pellets resuspended into appropriate plating media. Cells were plated (10⁶ per 2 ml medium per 35 mm Falcon plastic tissue culture dish) and cultured, without media changes, in an humidified 10% CO₂-air incubator at 37 °C. Cell counts (numbers of attached cells removed by trypsin) and amino acid analyses were performed by previously validated methods^{6,16}. Counting errors were ±2–10% (N = 3). a, Cell growth curves under various plating conditions: complete medium, male (■) or female cells (□) or female cells (■) or female cells (□). All other cells were from males with basal medium (●), basal medium plus 10 μg ml⁻¹ L-T₃ (X), or glucagon (○) or inosine (●), or insulin (◆) or hydrocortisone (▲) or inosine and insulin and hydrocortisone (×); complete medium minus serum (Δ). b, Growth curves (solid lines) of cells plated in complete medium ±0.4 mM L-arginine (■); without L-ornithine (●); or with ornithine replaced by 8 μM arginine (×) or by 0.008–0.4 mM putrescine (▲). Free arginine levels in culture media (except +0.4 mM arginine condition) are shown by dashed lines.

260 ng 'albumin' per 10⁵ cells per 6 h, respectively, whereas these rates measured by immunoprecipitation are 60,000 and 140,000 ³H-labelled 'albumin' c.p.m. per 10⁵ cells per 6 h. ³H-ornithine uptake is liver-specific because it is arginine-suppressible (Fig. 2) and detectable radioautographically as cytoplasmic grains⁶, mainly in monolayer aggregates⁴. Cells possessing this function (ornithine transcarbamylase) comprise 74 ± 3% (s.e.m.; N = 3) of the attached cell fraction 96–120 h post-plating. If log-phase cultures are labelled with both ³H-dT (as above) and ³H-ornithine (Fig. 2), radioautographic analyses show that 40 ± 2% (s.e.m.; N = 3) of ornithine-labelled cells also are in S-phase. Therefore, a substantial fraction of identifiable parenchymal hepatocytes traverse the 'cell-cycle' in this system. The extent to which DNA-synthesising cells not detectably labelled with ³H-ornithine (about 33% of the S-phase population) represent dedifferentiated hepatocytes and/or a contaminant population cross-fed via cell-cell interactions¹⁶ is as yet unknown.

Figure 2 also shows parallel increases in rates of ³H-ornithine uptake into cellular 'protein' and into released ³H-albumin during log growth; during stationary phase, these rates decrease to 30–40% and to about 80% of maximal, respectively. Moreover, arginine suppresses ³H-ornithine uptake into cellular 'protein' more efficiently than into released ³H-albumin. These observations could underlie intracellular compartmentalisation

of amino acid pools used for different protein synthetic processes in this system. This interpretation is complicated, however, by our inability rigorously to exclude the presence of heterogeneous cell types. Additional hepatic parenchymal cell functions present in this system include α_1 -foetoprotein, urea, tyrosine, and very low density lipoprotein biosynthesis (H. Leffert *et al.*, in preparation), and the hepatic microsomal hydroxylases¹⁷ (Fig. 3).

Conversion of ^{14}C -AAF into N -OH- ^{14}C -AAF (which is released into the medium) is shown in Fig. 3. This process appears liver cell-specific (e.g., primary adult rat pituitary or 3T3 cells lack this function) and is performed by viable cells, not by extracellular chemical and/or enzymatic mechanisms. Intracellular metabolism of N -OH- ^{14}C -AAF is suggested⁵ because cell-associated radioactivity, detected as 5% trichloroacetic acid-insoluble material, can be solubilised by trypsin, or KOH, or DNase treatment; moreover, unlabelled AAF specifically competes for ^{14}C -AAF uptake; and conversion is modified by gonadal steroids (H. Leffert *et al.*, in preparation). Relative proportions of hydroxylated metabolites released *in vitro* (N -OH-AAF = 2%, 3-, 5-, 7-, and 1-OH-AAF = 17, 15, 7, and 1%, respectively) simulate urinary metabolite distributions reported for male rats fed ^{14}C -AAF (ref. 18). This determination was independently confirmed using a second solvent system which, in addition to resolving N -OH- ^{14}C -AAF,

Fig. 2 Albumin production and ^3H -ornithine uptake in adult liver cell cultures. Male cultures were established using complete medium (see Fig. 1). Media were aspirated at various times, the dishes washed twice with 2 ml complete medium (minus ornithine) and then fed 2 ml similar medium containing 25 μCi ^3H -3-dl-ornithine (1 mCi per 68 μg ; New England Nuclear) without (open symbols) or with (shaded symbols) 0.4 mM arginine for 6–8 h. Harvested fluids were pretreated with an unrelated antigen-antibody system, to remove nonspecific radioactivity adventitiously adsorbed to specific immune-complexes, and then assayed for ^3H -labelled rat albumin ($\square$ — $\square$) by immunoprecipitation with purified monospecific goat anti-rat albumin antibody¹⁵. About 20% of the total radioactivity material present in the culture fluids was acid-insoluble; of this, 20–30% was detected as 'albumin' either by the above procedure or by isoelectric focusing together with authentic rat albumin¹⁵. Culture monolayers were assayed¹⁴ for precursor uptake into acid-insoluble material ($\circ$ — $\bullet$). A similar pattern is observed if uptake into 90 $^\circ\text{C}$ (20 min) heat-stable acid insoluble material is determined¹⁴; about 40% of the counts are solubilised at any time under these conditions. Measurement errors were $\pm 10\%$.

Fig. 3 N -hydroxylation of 2-acetylaminofluorene by cultured adult liver cells. Male cultures 5–6-d-old (Fig. 2) were treated 48 h with 20 μl of a 95% v/v ethanol solution of ^{14}C -9-AAF (0.1 mCi per 0.55 mg; 20 $\mu\text{Ci ml}^{-1}$; 100 $\mu\text{g ml}^{-1}$ (New England Nuclear); 96–98% of the radioactivity is found in the medium after 48 h. Two ml cell-free culture medium was added to 3 ml 1 M sodium acetate buffer, pH 6.0, containing 50 μl CHCl_3 and 2.5 mg each of β -glucuronidase and α -amylase (61 and 55 U mg^{-1} , respectively; Sigma)²⁰ and incubated for 24 h at 37 $^\circ\text{C}$. Acid-washed ether extracts of the resulting solution, which removed about 65% of the counts, were chromatographed^{19,20} on silica gel 60 plates 5×20 cm; Brinkman) using benzene/acetone (8/2) and developed four times; recovery was $\geq 98\%$. Radioactivity present in 5×0.5 cm strips scraped into plastic vials containing 10 ml 'cocktail' (3.79 l toluene, 160 ml Liquifluor, 158 g Cab-O-Sil (Eastman Kodak) was detected by scintillation counting with measurement errors of $\pm 0.2\%$. R_f values of authentic N -OH-AAF (cross-hatched rectangular bar), ring-hydroxylated metabolites, ^{14}C -AAF and aminofluorene (AF) (solid bars) are indicated above radioactive profile (corrected for background of 8 c.p.m.). Standards were detected with Folin/ Na_2CO_3 and p -nitro-methylbenzaldehyde reagents¹⁹. Peak fractions (arrow indicates position of N -OH- ^{14}C -AAF) were confirmed identical with authentic standards by rechromatography using a second system (chloroform/methanol, 97/3; development three times). Radioactivity in both systems which cochromatographed with authentic N -OH-AAF was five to eightfold greater than background.

separates 1- and 3-position ring-hydroxylated metabolites from AAF (see legend to Fig. 3)^{19,20}.

The critical interactions required of hormones, nutrients and carcinogens (at cellular and subcellular targets) to alter proliferative control are as yet unknown. This system may provide a useful tool to study this problem.

Activation of human leukocyte elastase by human α_2 -macroglobulin

PROTEOLYSIS and its biological control in the pathogenesis of disease states involving inflammation and tissue injury have become areas of intensive study^{1,2}. Because of their probable involvement in the pathogenesis of emphysema, the elastolytic enzymes derived from neutrophils have received particular attention^{3–6}. Among the principal protease inhibitors in blood, α_1 -antitrypsin (α_1 -AT) serves as the main inhibitor controlling the activity of elastase and other serine proteinases, whereas α_2 -macroglobulin (α_2 -M) is believed to function primarily as a means of removing elastase and other proteinases from the circulatory system via the reticuloendothelial system^{7,8}. During studies of the interaction of various inhibitors with elastase isolated from purulent sputum⁹, it was noted that the activity of this enzyme towards certain synthetic substrates was markedly enhanced in the presence of α_2 -M. We present here a study of this activation. It is possible that activation of elastase by α_2 -M may be of physiological significance, particularly under those conditions where a deficiency of α_1 -antitrypsin is known to be a predisposing factor towards chronic obstructive pulmonary disease¹⁰.

Leukocytic elastase was prepared from purulent sputum⁹ and was comprised of three isozymes with no other impurities detectable by gel electrophoresis. For purposes of calculation, however, this mixture of enzymes was assumed to be a single entity with a molecular weight of 27,000 (ref. 9). human α_2 -M was prepared from plasma according to Harpel¹¹ and was judged to be at least 98% homogeneous by gel electrophoresis¹². Its molecular weight, as determined by sedimentation equilibrium, was 726,000. Although the activity of the elastase towards casein was almost completely inhibited by a twofold molar excess of α_2 -M, its activity towards the synthetic substrate Suc-(Ala)₃-Nan (*N*-succinyl-L-alanyl-L-alanyl-L-alanine-4-nitroanilide) was dramatically enhanced in the presence of α_2 -M (Fig. 1). Extrapolation of the linear segments of the curve in Fig. 1 shows maximum activation (15-fold) to occur when the weight ratio of α_2 -M to elastase is approximately 12 to 1. Based on the molecular weight values referred to above, this weight ratio corresponds to a molar ratio of 1:2.2. From Lineweaver–Burk plots, it was calculated that the k_{cat}

in the presence and absence of α_2 -M was 4.0 s^{-1} and 0.45 s^{-1} respectively, whereas the K_m was $1.82 \times 10^{-3}\text{ M}$ both in the presence and absence of α_2 -M. The fact that there was only a ninefold enhancement of the k_{cat} of elastase in the presence of α_2 -M compared to the 15-fold increase in the activity ratio (Fig. 1) may be due in part to the fact that in the latter case activity was based on end-point measurements at 37°C whereas the kinetic analysis was based on measurements of initial rates at 25°C .

Table 1 summarises data pertaining to the effect of α_2 -M on the activity of leukocyte elastase towards various other synthetic substrates. In addition, a comparison has been made with porcine pancreatic elastase (Worthington) in the case of Suc-(Ala)₃-Nan. The greatest degree of activation of the leukocytic elastase by human α_2 -M was observed with Suc-(Ala)₃-Nan as the substrate. Replacing the acidic succinyl group with an acetyl or a butoxy-carbonyl group produced a lesser degree of activation, and the substitution of the aromatic component of the ester linkage by a methyl group caused little, if any, activation. Of further interest is the fact that the activity of porcine pancreatic elastase towards Suc-(Ala)₃-Nan was actually inhibited by human α_2 -M.

Experiments were performed to ascertain whether this phenomenon of activation could be demonstrated with sera obtained

Fig. 1 Activation of human leukocytic elastase towards Suc-(Ala)₃-Nan by human α_2 -M. Reaction mixtures contained 100 μl of enzyme solution ($18\text{ }\mu\text{g ml}^{-1}$) with various levels (0–100 μl) of α_2 -M solution (1 mg ml^{-1}) in a final volume of 1.2 ml 0.2 M Tris-HCl–0.5 M NaCl, pH 8. After pre-incubation for 15 min at 37°C , 150 μl of substrate solution (0.01 M Sac-(Ala)₃-Nan; ref. 13) were added and the incubation continued for a further 20 min at the same temperature. Reaction was terminated by adding 150 μl glacial acetic acid, and the absorbance read at 410 nm. Insert is plot of the increase in absorbance (absorbance of enzyme with α_2 -M minus absorbance of enzyme without α_2 -M) as a function of the quantity of α_2 -M added. In the larger figure, the activity ratio (ratio of absorbance of enzyme with α_2 -M to absorbance of enzyme without α_2 -M) is plotted as a function of the ratio (by weight) of α_2 -M to enzyme.

Table 1 Effect of human α_2 -M on the activity of elastases towards various synthetic substrates

Substrate*	Source of elastase	Specific activity†		Ratio + α_2 -M / - α_2 -M
		- α_2 -M	+ α_2 -M	
Suc-(Ala) ₃ -Nan	Leukocytes (human)	0.3	4.6	15.3

†Units of activity per mg enzyme where one unit of activity is equivalent to the hydrolysis of 1 μ mol of substrate per min under the conditions specified for each assay.

from normal (phenotype *MM*) and α_1 -AT-deficient (phenotype *ZZ*) individuals. Data were obtained with sera from two patients who had been diagnosed as being α_1 -AT-deficient homozygotes (phenotype *ZZ*) and with sera from two normal individuals (phenotype *MM*) (Table 2). Both the normal and deficient sera completely inhibited the activity of the leukocyte and pancreatic elastases toward elastin. When the synthetic substrates were tested, the residual activity of both elastases was consistently higher in the case of the *ZZ* sera. Especially noteworthy, however, is the fact that there was a fourfold increase in the activity of the leukocyte elastase when tested against Suc-(Ala)₃-Nan in the presence of the *ZZ* sera. This observation can be readily explained by the fact that the predominant protease inhibitor in *ZZ* sera is α_2 -M rather than α_1 -AT, a situation which, on the basis of our previous experiments, would be expected to augment the activity of the leukocytic elastase towards Suc-(Ala)₃-Nan.

α_2 -M is known to interact with a wide variety of proteases to form complexes which are generally inactive towards large molecular weight substrates but which exhibit little or no loss in activity towards low molecular weight substrates¹⁷. Although there have been occasional reports of an enhancement of the activity of trypsin (bovine)¹⁸, chymotrypsin (bovine)¹⁹, and elastase (porcine)²⁰ by α_2 -M (human), the degree of activation has usually been quite small (10–50%) compared to that which we observed with our system (900–1,500%). We attribute this difference to two factors; first, both the enzyme and α_2 -M which we used were derived from the same species of animal; and second, the substrate used had an aromatic moiety as part of the ester or amide linkage and had an acidic group blocking the terminal amino group of the substrate. It is interesting to note that Nakamura *et al.*²¹ have also reported a two to threefold activation of bovine chymotrypsin by bovine α_2 -M on substrates possessing these same attributes. In agreement with the data of Nakamura *et al.*²¹ we also found that maximum activation of leukocyte elastase towards a synthetic substrate was produced when two molecules of the enzyme were complexed by one molecule of human α_2 -M. Ohlsson and Laurell⁸ have reported a similar ratio for the inactivation of

leukocyte elastase by human α_2 -M with elastin as the substrate.

At the moment we are unable to explain this phenomenon of activation, but any explanation that is offered should take into account the hypothesis that the complexation of proteases with α_2 -M is probably a two-step process involving an initial cleavage of a critical peptide bond followed by a conformational change which serves to entrap the enzyme¹⁷. Macromolecular substrates are thus prevented from reaching the enzyme, whereas small synthetic substrates are not so restricted. Particularly puzzling is the fact that the K_m , which reflects the affinity of the enzyme for the substrate, Suc-(Ala)₃-Nan, is not affected by α_2 -M despite a marked enhancement in the catalytic efficiency of the enzyme as measured by k_{cat} . Since the latter effect seems to depend on the presence of an aromatic and an acidic group on the substrate molecule, it may be that the conformational change in α_2 -M which serves to entrap the enzyme uncovers a hydrophobic cavity which, in conjunction with a positively charged group, orients the substrate in a position which is more favourable for acylation or deacylation by the enzyme. Jacquot-Armand and Krebs²² have in fact shown that α_2 -M which has interacted with trypsin undergoes a conformational change which exposes an apolar region in the α_2 -M molecule. Furthermore, it seems that the most striking effects are produced when the enzyme and α_2 -M are derived from the same species of animal—the reason for this remains obscure.

Whether this phenomenon of activation is of any physiological significance is open to conjecture. One observation which may be pertinent in this respect is the reference by Meyer *et al.*²³ to unpublished results showing that pancreatic elastase (porcine) was capable of digesting chemically solubilised elastin even when complexed with α_2 -M. If the leukocytic elastase were to behave in a comparable fashion, then its complexation with α_2 -M might actually serve to augment its ability to degrade tropoelastin secreted into the extracellular space prior to the formation of cross-linkages found in elastin²⁴. In normal individuals this destructive effect on the synthesis of elastin could be held in check by adequate levels of α_1 -AT. On the other hand, as suggested by our *in vitro* experiments with *ZZ* sera, in individuals who are deficient in α_1 -

Table 2 Effect of *MM* and *ZZ* sera on the activity of leukocyte and pancreatic elastases on various substrates *

Substrate†	Source of elastase	Phenotype‡			
		M.G.	<i>MM</i> P.L.	<i>ZZ</i> J.H.	N.G.
Elastin-rhodamine	Leukocytes (human)	0	0	0	0
	Pancreatic (porcine)	0	0	0	0
Suc-(Ala) ₃ -Nan	Leukocytes (human)	55	70	400	400
	Pancreatic (porcine)	8	13	40	45
Boc-Ala-ONp	Leukocytes (human)	10	—	50	48
	Pancreatic (porcine)	15	11	55	49

*Activities are expressed as % of controls without serum.

†Activity towards elastin-rhodamine was measured according to Rinderknecht *et al.*²⁵ using levels of 1.4 and 12.5 μ g of porcine and leukocyte elastase respectively in each assay mixture. Assays on synthetic substrates were performed as described in Table 1 using levels of 1.4 and 1.33 μ g of porcine and leukocyte elastase respectively in each assay system. The level of serum employed in these assays was 1.0 μ l serum per μ g enzyme in case of *MM* sera and 4.5 μ l serum per μ g enzyme for *ZZ* sera.

‡The trypsin inhibitor capacity of the serum of each individual was assayed on *N*-benzoyl-DL-arginine-*p*-nitroanilide²⁶, and the following values, expressed as % of a standard reference serum (supplied by Dr John A. Pierce) were obtained for the four individuals: M.G., 119; P.L., 100; J.H., 32; N.G., 25.

AT a greater proportion of the elastase would be expected to complex with α_2 -M leading to a further exacerbation of the destruction of lung tissue.

This work was supported by the US NIH. We thank Cynthia A. Curasi for technical assistance and Dr Ronald Roberts for a gift of human α_2 -M.

Effects of iron chelators and iron overload on *Salmonella* infection

INCREASED susceptibility to infectious disease is observed in iron-overloaded states such as β -thalassaemia major and in haemolytic states such as sickle cell disease or Bartonellosis^{1,2}. The virulence of *Escherichia coli*, *Listeria monocytogenes*, *Salmonella typhimurium* and other pathogens can be increased by administration of iron compounds to the host, and transferrin-induced inhibition of bacterial growth can be reversed by saturating transferrin^{3–6}. Plasma and secretory iron-binding proteins such as transferrin and lactoferrin may function in host defence by limiting the availability of iron to invading pathogens⁷. Many microorganisms synthesise iron-binding compounds when little iron is available⁸; these compounds may compete with host iron-binding mechanisms. We report here the effects of iron-chelating drugs on this competition for iron in *S. typhimurium* infection in normal and iron-overloaded mice. Desferrioxamine (DF), a hydroxamic acid, and 2,3-dihydroxybenzoic acid (2,3-DHB), a phenolic iron chelator, represent two classes of iron-chelating compounds which are being tested in chelation therapy for iron overload. Our data provide evidence that DF increases iron availability to wild type *S. typhimurium*, promoting bacterial growth and thus enhancing virulence.

Male Swiss-Webster mice were iron overloaded by intraperitoneal injections of 0.25 ml of human blood heated to 50 °C for 5 min. Injections were given once a day, five

times a week for 8 weeks, so that mice received more than 3 blood volumes before infection. After overloading, the liver, spleen and pancreas of several mice were examined histologically. Liver and spleen iron was also measured by atomic absorption spectrophotometry and compared with that of control mice. Iron overloading was confirmed in sections stained with Prussian blue, which revealed increased iron stores in the liver, spleen and pancreas. Concentrations of iron in normal mice were 159.4 ± 12.6 mg per liver and 44.6 ± 3.5 mg per spleen compared with 230.2 ± 8.8 mg per liver and 70.2 ± 8.8 mg per spleen in iron-overloaded animals.

Wild type *S. typhimurium* was obtained from a clinical microbial laboratory and found to grow normally on low-iron medium. A mutant of *S. typhimurium* (TA2701) blocked in the synthesis of enterobactin, its own natural iron chelator, was unable to grow on low-iron media in the presence of DF but would grow in response to 2,3-DHB (refs 10, 11). After passage through six generations of mice to increase its virulence, the mutant retained its growth characteristics on low-iron medium. Organisms for injection were cultured overnight in nutrient broth, washed three times and diluted in sterile saline.

Iron-overloaded and normal mice received an intraperitoneal injection of either the wild type or mutant *S. typhimurium* and were divided into three groups of six. One group received DF, one received 2,3-DHB and the third received no drug. Both drugs were injected in doses of 25 mg kg⁻¹ every 6 h, beginning 24 h before infection and continuing throughout the experiment. Uninfected groups of six iron-overloaded or normal mice received DF or 2,3-DHB in the same doses. The number of survivors from each group was recorded at 6-h intervals.

Cultured post mortem liver specimens yielded organisms with the same growth characteristics on low-iron medium as the infecting organism. This confirms that the pathogen injected was the cause of death. All uninfected mice treated with 2,3-DHB or DF survived.

Figure 1 shows the effects of iron overloading on the survival probability of animals not receiving an iron-chelating drug. In the groups infected with wild type *S. typhimurium*, iron overloading caused a significant reduction in survival probability. Similarly, in the groups treated with DF and 2,3-DHB (not shown), iron overloading increased virulence in wild type infection, the effect being

Fig. 1 Survival probabilities against time of normal (○) and iron-overloaded (●) mice infected with *S. typhimurium*. a, Wild type, 10^8 bacteria, $P < 0.02$; b, wild type, 10^5 bacteria, $P < 0.02$; c, mutant TA2701, 10^4 bacteria, not significant; d, mutant TA2701, 10^6 bacteria, not significant. Probabilities were determined by the Stromgen method of life-table analysis¹². Differences in the probability plots were compared for significance at the maximum deviation using a two-sided hypothesis¹³.

most pronounced with DF. In untreated mice infected with the mutant (Fig. 1b), iron overloading had no effect on survival probabilities. Similarly, iron overloading produced no reduction in survival in DF-treated animals infected with the mutant. But in animals infected with the mutant and treated with 2,3-DHB, survival was reduced by iron overloading (Fig. 2).

Figure 3 shows that in wild type infection, survival of both normal and iron-overloaded animals was reduced significantly by DF. This effect was absent or reversed in animals infected with the mutant. The reversal of the DF effect—prolongation of survival—was seen in both normal and iron-overloaded animals given the lower infecting dose.

Wild type *S. typhimurium* which grow in low-iron media can do so, at least in part, because they synthesise an iron chelator such as enterobactin¹⁴. *In vivo*, if iron overloading produces an increase in host iron available to the pathogen, wild type growth rate and thus virulence would be expected to increase. This expectation was fulfilled in control and drug-treated animals which were iron overloaded and infected with the wild type *Salmonella*. If the ability to synthesise an iron chelator is absent, as in mutant TA2701, increased availability of iron in the host should have no effect on virulence. This is confirmed by Fig. 1b. The only mutant-infected animals to show reduced survival with iron overloading were those treated with 2,3-DHB. This was anticipated by the *in vitro* growth characteristics of TA2701, which can utilise 2,3-DHB as an iron chelator.

DF has been shown to increase the growth rate of *S. typhimurium* in defined medium¹⁰, and Fig. 3 confirms this effect *in vivo*. DF seems to increase the availability of iron to multiplying wild type *Salmonella* and thus to reduce the survival of the host. This effect is augmented by iron overloading. On the other hand, treatment of the mutant-infected animals with DF produced no significant increase in virulence. At the lower levels of infection in both normal and iron-overloaded animals, DF significantly prolonged survival. These results support the *in vitro* observation that the mutant cannot utilise ferrioxamine. Thus by sequestering iron and making it unavailable to the mutant, DF retards its growth and decreases its virulence.

These experiments provide evidence that DF, which is used to treat iron overload, may increase the virulence of *S. typhimurium* by increasing the iron available to the bacteria and thereby promoting growth. The results also suggest that an iron chelator not utilisable by micro-organisms decreases the iron available for bacterial growth

Fig. 2 Survival probabilities of normal (○) and iron-overloaded (●) mice treated with 2,3-DHB and infected with mutant TA2701. 2,3-DHB was synthesised in our laboratory⁹. a, 10^6 bacteria, $P < 0.02$; b, 10^4 bacteria, $P < 0.01$.

and thus decreases the virulence of invading pathogens.

This work was supported by grants from the NIH and the National Foundation-March of Dimes. We thank Drs M. Luckey and Hugh Akers for the mutant TA2701 and the Clinical Microbiology Laboratory at New York Hospital for wild type *Salmonella*.

GABA receptor binding with $^3\text{H}(+)\text{bicuculline-methiodide}$ in rat CNS

NEUROTRANSMITTER receptors might be identified biochemically in binding studies with synaptic membrane preparations using labelled receptor agonists or antagonists as ligands¹. In attempts to identify the GABA receptor ^3H -GABA has been used as ligand. ^3H -GABA, however, also binds to glial and neuronal GABA uptake sites and to enzymes metabolising GABA. Thus, Na^+ -dependent ^3H -GABA-binding^{2,3}, in contrast to Na^+ -independent ^3H -GABA-binding is possibly not related to the GABA receptor⁴. In the present investigation the GABA antagonist $^3\text{H}(+)\text{bicuculline-methiodide}$ ($^3\text{H}(+)\text{BM}$) was used as ligand, which in contrast to bicuculline, is chemically sufficiently stable⁵. $(+)\text{Bicuculline}$ and its *N*-methyl-derivative antagonise reversibly and rather selectively the inhibitory synaptic action of GABA in the central nervous system (CNS) (refs 6, 7) without affecting the uptake or release of GABA or enzymes metabolising GABA (refs 8, 9). Thus $^3\text{H}(+)\text{BM}$ might be more suitable for GABA receptor binding studies than GABA itself.

The characteristics of specific $^3\text{H}(+)\text{BM}$ binding in the present study are compatible with the properties of the GABA receptor expected from neurophysiological data. Specific $^3\text{H}(+)\text{BM}$ -binding was saturable, stereospecific and maximally enriched in the synaptic membrane fraction. Among a variety of compounds tested only GABA, GABA agonists and GABA antagonists were potent competitors for $^3\text{H}(+)\text{BM}$ specific binding sites.

Routine binding assays were performed by incubating crude cerebellar synaptic membranes with 5 nM $^3\text{H}(+)\text{BM}$ in the absence and presence of exogenous GABA. 'Specific binding' of $^3\text{H}(+)\text{BM}$ to the membranes was obtained by subtracting from the radioactivity bound in the absence of GABA ('total binding') the amount not displaceable by high concentrations of GABA (50 μM ; 'non-specific binding').

Among the different subcellular fractions of cerebellum

tested, the highest specific $^3\text{H}(+)\text{BM}$ binding was found in the crude synaptic membrane fraction (Table 1). The specific activity (d.p.m. per mg protein) of $^3\text{H}(+)\text{BM}$ specifically bound in this fraction was about 2.5 times that of the whole homogenate and similar to that of the P_2 -fraction containing intact synaptosomes.

Specific $^3\text{H}(+)\text{BM}$ binding to the cerebellar synaptic membrane fraction was saturable, half-maximal binding occurring at 380 ± 20 nM. By contrast, non-specific binding, represented by the radioactivity bound in the presence of 50 μM GABA, was not saturable and increased linearly with increasing $^3\text{H}(+)\text{BM}$ concentration. Similarly, displacement of $^3\text{H}(+)\text{BM}$ by non-radioactive $(+)\text{BM}$ was half-maximal at 218 ± 21 nM (Table 2, Fig. 2), correlating well with the value obtained in the saturation experiments using $^3\text{H}(+)\text{BM}$ alone.

The stereospecificity of $^3\text{H}(+)\text{BM}$ binding is shown by the finding that the neurophysiologically inactive isomers $(-)\text{bicuculline}$ and $(-)\text{BM}$ (ref. 10) had only about 1/800 and 1/400 the affinity of the respective $(+)\text{isomers}$ for the $^3\text{H}(+)\text{BM}$ binding sites, as indicated by their K_i values (Table 2, Fig. 1). Furthermore, when $^3\text{H}(-)\text{BM}$ was used as ligand (5 nM), no displacement with 50 μM non-radioactive $(+)\text{BM}$, GABA, muscimol, 3-aminopropane-sulphonic acid or $(-)\text{BM}$ was observed, indicating that the neurophysiologically inactive isomer $(-)\text{BM}$ did not bind to the $(+)\text{BM}$ binding sites at the ligand concentration used. In addition, since the excitatory action of $(+)\text{BM}$ found *in vivo* is not stereospecific¹⁰, this action does not seem to be reflected in the *in vitro* $^3\text{H}(+)\text{BM}$ binding studies presented here.

The high affinity of $(+)\text{bicuculline}$ ($K_i = 68$ nM) for the $(+)\text{BM}$ binding sites (Table 2, Fig. 1) corresponds to its high potency as a GABA antagonist *in vivo*; $(+)\text{bicuculline}$ is about 60 times less potent in competing for Na^+ -independent ^3H -GABA binding sites (rat whole brain⁴) and even 1,000 times (rat cerebellar cortex³) and 70,000 times (crayfish muscle²) less potent in competing for Na^+ -dependent ^3H -GABA binding sites.

The findings that $(+)\text{BM}$ is more potent than $(+)\text{bicuculline}$ as a GABA antagonist microelectrophoretically⁷ and as a convulsant¹¹ are difficult to explain on the basis of their potencies in competing for $^3\text{H}(+)\text{BM}$ binding sites (Table 2, Fig. 1). However, the high lipid solubility of bicuculline might influence its concentration at the receptor or binding sites to a varying degree under different experimental conditions. In addition, there might be a

Table 1 Subcellular distribution of specifically bound $^3\text{H}(+)\text{BM}$ in rat cerebellum

Fraction	Specifically bound $^3\text{H}(+)\text{BM}$ (d.p.m. per mg protein)	(as % of total binding)	Specifically bound $^3\text{H}(+)\text{BM}$ per entire fraction (d.p.m.)

The subcellular fractions of cerebellum (male SPF rats, 150-200 g) were prepared according to Zukin *et al.*⁵. The binding assay was performed in triplicate as described in Fig. 1 (5 nM $^3\text{H}(+)\text{BM}$ and 2 mg protein per assay in the presence or absence of 50 (μM) GABA). 'Total binding' refers to the radioactivity bound in the absence of GABA, 'specifically bound' to that displaceable by GABA. The values are the means $\pm$ s.e.m. from three experiments.

Fig. 1 Competition for the $^3\text{H}(+)\text{BM}$ specific binding sites by (+) bicuculline (▲); (—) bicuculline (*) (●); (+) bicuculline methiodide (○); (—) bicuculline methiodide (○); (±) laudanosine (■). Increasing concentrations of the displacing agent were added to tubes containing in a 2 ml volume cerebellar synaptic membranes (2 mg protein), 5 nM $^3\text{H}(+)\text{BM}$, 50 mM Tris-HCl buffer pH 7.4 and 50 mM NaSCN. After incubation at 25 °C for 15 min—at which time equilibrium had been reached—and centrifugation at 48,000 g for 10 min, the pellet was rinsed by superfusion with 5 ml and then 10 ml of ice-cold 50 mM Tris-HCl buffer pH 7.4. After dissolving the pellet in 2 ml Protosol, scintillant was added and the radioactivity counted (counting efficiency 38%). The points are the means of triplicate determinations of a typical experiment with standard errors of the mean ranging from 0.1 to 2.0%. The corresponding K_i values are given in Table 2. $^3\text{H}(+)\text{BM}$ and $^3\text{H}(-)\text{BM}$ (radiochemically pure > 99%; specific activity 8.0 and 13.0 Ci per mmol respectively) were prepared by methylation¹⁵ of (+) and (—) bicuculline with ^3H -labelled methyl iodide synthesised according to Schwob and Würsch¹⁶. (—) Bicuculline was synthesised according to Teitel *et al.*¹⁷. Crude synaptic membrane fractions were prepared according to Enna and Snyder⁴ and stored frozen at -30 °C for 1–5 d before use. Fresh and frozen membranes gave similar results. There was no degradation of bound or free $^3\text{H}(+)\text{BM}$ during the incubation.

contribution from the excitatory effect of (+)BM *in vivo* or a regional or species difference in the potency of the two compounds.

In agreement with the neurophysiological potency⁶, the GABA agonist muscimol was more, imidazole acetic acid less potent in competing for $^3\text{H}(+)\text{BM}$ binding sites than GABA itself, while 3-aminopropanesulphonic acid despite

Fig. 2 Competition for the $^3\text{H}(+)\text{BM}$ specific binding sites by GABA and GABA agonists. The binding assay was performed as described in Fig. 1 (5 nM $^3\text{H}(+)\text{BM}$; 2 mg cerebellar synaptic membrane protein per assay). Points are means of triplicate determinations in a typical experiment with s.e.m. values of 0.1–2.5%. The corresponding K_i -values are given in Table 2. Muscimol (▲); 3-aminopropanesulphonic acid (●); GABA (*) (○); imidazole acetic acid (■).

Table 2 Inhibition of specific $^3\text{H}(+)\text{BM}$ -binding to synaptic membranes of rat cerebellum by various compounds

Compound	K_i (nM)
GABA antagonists	
(+) Bicuculline	68.2 ± 2.5
(+) Bicuculline-methiodide	218 ± 21
GABA agonists, amino acids and related compounds	
Muscimol	58.1 ± 6.8
GABA	420 ± 55
3-Aminopropanesulphonic acid	490 ± 70
Imidazole acetic acid	3,830 ± 320
β-Alanine	58,700 ± 6,300
Glutamate	n.i.
Aspartate	n.i.
α-Alanine	n.i.
Glycine	n.i.
Proline	n.i.
Taurine	n.i.
Nipecotic acid	n.i.
Aminooxyacetic acid	n.i.
Isoniazid	n.i.
Other compounds	
Strychnine	3,500 ± 360
(±) Laudanosine	33,700 ± 1,600
(—) Bicuculline-methiodide	52,800 ± 5,200
(—) Bicuculline	59,300 ± 3,500

'No inhibition' (n.i.) refers to concentrations up to 10^{-4} M. Further compounds without inhibitory effect at least up to 10^{-8} M include 2,4-diaminobutyrate, morphine, nialamide, kainic acid, chlordiazepoxide, diazepam, pentobarbital, baclofen, oxotremorine, physostigmine and Ro 4-1284, a water-soluble benzoquinolizidine derivative with reserpine-like action¹⁸. Haloperidol and chlorpromazine displaced 18% of the specifically bound $^3\text{H}(+)\text{BM}$ at 10^{-5} M. Inhibition of $^3\text{H}(+)\text{BM}$ -binding (5 nM; 2 mg cerebellar membrane protein per assay) was measured at six to 15 concentrations of each compound in triplicate as described in Fig. 1. The 50% inhibitory concentration (IC_{50}) was calculated by log logit analysis and converted to K_i according to the equation $K_i = \text{IC}_{50}/(1 + C/K_D)$, where C is the concentration of radioactive ligand and K_D its dissociation constant. The values are the means ± s.e.m. of three experiments. For some compounds typical inhibition curves are shown in Figs 1 and 2.

its higher neurophysiological potency¹² was similar to GABA in its competing potency (Table 2, Fig. 2). As drug potencies can differ in different species and/or brain areas, however (as shown for muscimol and bicuculline⁶), a more quantitative correlation has to await binding experiments and neurophysiological studies to be performed in the same species and brain region.

It should be noted that (±)laudanosine, a neurophysiologically inactive analogue of bicuculline^{6,7}, is also inactive as inhibitor of specific $^3\text{H}(+)\text{BM}$ binding (Table 2, Fig. 1). Strychnine, with an affinity constant for the glycine receptor of 2 nM (ref. 13), required concentrations 1,700 times higher to reduce specific $^3\text{H}(+)\text{BM}$ binding by 50%.

In studies of the distribution of specifically bound $^3\text{H}(+)\text{BM}$ in different brain regions the highest levels were found in cerebral cortex (82.7 ± 1.4 fmol per mg protein) and cerebellum (67.6 ± 1.2), followed by hippocampus (57.1 ± 1.5), midbrain (54.2 ± 2.5), hypothalamus (49.4 ± 2.1) and striatum (39.2 ± 1.9). The lowest levels were found in medulla oblongata-pons (16.1 ± 1.7) and spinal cord (8.7 ± 2.0). These regional differences do not correlate well with the regional levels of endogenous GABA in rat CNS¹⁴. In other receptor systems, however, there are also discrepancies between receptor densities and endogenous transmitter levels. Presumably, the surface area and receptor density of the postsynaptic membrane vary independently of the endogenous transmitter levels in different areas of brain¹. The regional distribution of specific $^3\text{H}(+)\text{BM}$ -binding is largely similar to that of Na-independent ^3H -GABA-binding with the cerebellum as main exception which shows twice the GABA-binding of cerebral cortex⁴.

The GABA agonists tested so far in Na⁺-independent

³H-GABA-binding⁴ and in ³H(+)-BM-binding (GABA, 3-aminopropanesulphonic acid, imidazole acetic acid) show a higher affinity for ³H-GABA binding sites than for ³H(+)-BM binding sites. The inverse relationship holds for (+)-bicuculline, the only GABA antagonist compared so far. This finding may be explained by a receptor model in which agonists and antagonists bind to two different receptor sites possibly with a mutual negative cooperative interaction. Binding of an agonist might reduce the binding affinity of an antagonist and vice versa. But as the rank orders of regional ³H-GABA-binding and ³H(+)-BM-binding are not identical, we cannot exclude the possibility that ³H-GABA and ³H(+)-BM label different types of GABA receptors at least in some rat brain areas.

We thank Drs Schwob and W Würsch for synthesising (+)- and (-)-³H-bicuculline-methiodide, and Drs Haefely and DaPrada for helpful criticism.

Direct detection of depolarisation-induced release of ATP from a synaptosomal preparation

SEVERAL groups have shown that ATP is released from neural tissues during depolarisation, where it or its metabolites might function as neurotransmitters or neuromodulators¹. They measured radiolabelled adenosine derivatives in perfusates following depolarisation of their preparations. Recently, Israel *et al.*² described a method for continuously and directly detecting the release of ATP from the electric organ of *Torpedo marmorata* after stimulation of its motor nerve. I have used a modification of this technique to study the depolarisation-induced release of ATP from a purified synaptosomal fraction prepared from rat brain. I report here that depolarisation of synaptosomes elicits a release of ATP which can be directly and continuously detected by this technique.

Synaptosomes were incubated in a Krebs-Henseleit bicarbonate medium containing firefly luciferin-luciferase and depolarised by elevating the extracellular K⁺ or by adding veratridine. Veratridine depolarises excitable tissues, including synaptosomes, by selectively opening Na⁺ channels³⁻⁶. Released ATP was detected by measuring the light emitted with a photomultiplier. Supplementing the luciferin⁷ greatly enhanced the sensitivity of detection of ATP. Preliminary experiments showed that the assay system was specific for ATP, in that similar concentrations of adenosine, AMP or ADP did not produce chemiluminescence.

Depolarisation of synaptosomes caused a release of ATP

which could be directly and continuously monitored. Elevating the extracellular KCl concentration by 23 mM caused a rapid release of ATP from synaptosomes, indicated by an increased emission of light (Fig. 1a). This effect was probably not due to the increased tonicity of the incubation medium, since increasing the extracellular concentration of NaCl by 23 mM caused a fall in the background chemiluminescence. Choline chloride and LiCl produced similar decreases in chemiluminescence (not shown). The response to elevated extracellular K⁺ was not prevented by the specific Na⁺ channel blocker, tetrodotoxin⁸⁻¹⁰ (Fig. 1b), showing that this effect was not mediated by the opening of Na⁺ channels in the synaptosomal membranes. This is not surprising, since one would expect elevated extracellular K⁺ to depolarise the synaptosomes directly without altering the Na⁺ and K⁺ permeabilities^{11,12}.

The depolarisation-induced release of a number of putative neurotransmitters from brain preparations has been

Fig. 1 K⁺-induced release of ATP from synaptosomes. Synaptosomes were prepared from the whole brains of four adult male Wistar rats (200-250 g) and isolated on sucrose density gradients as described previously⁸. They were finally suspended to a final volume of 8 ml with Krebs-Henseleit bicarbonate medium containing 111 mM NaCl, 26.2 mM NaHCO₃, 1.2 mM NaH₂PO₄, 4.7 mM KCl, 1.8 mM CaCl₂, 1.2 mM MgCl₂, 11 mM glucose and gassed periodically with 95% O₂: 5% CO₂ to maintain a pH of 7.4. The suspension was preincubated at 37 °C for 30 min and a 0.5 ml portion placed in a 6 × 50 mm cylindrical cuvette; 20 µl of fortified luciferin-luciferase enzyme preparation were added. The enzyme preparation was prepared daily by adding 0.2 ml synthetic D-luciferin (5 mg per ml H₂O, Sigma; stored at -20 °C) to 0.2 ml of crude firefly lantern extract (50 mg Sigma FLE-50 in 2 ml H₂O, prepared daily). The cuvette was placed in the reaction chamber of a 'Chem-Glow' chemiluminometer (American Instrument Co.) and let stand until a reasonably constant level of chemiluminescence was attained, usually 1-2 min. Even without gassing, the pH of the suspension remained at 7.5-7.6 throughout the incubation. *a*, KCl was increased by 23 mM by injecting 10 µl of a 1.25 M KCl solution into the cuvette with a Hamilton syringe. After the chemiluminescence had returned to its resting level, 5 µl of a 10⁻⁷ M ATP solution in incubation medium were injected into the cuvette to give a final ATP concentration of 9.4 × 10⁻¹⁰ M. The experiment was repeated using NaCl instead of KCl. *b*, Injecting 10 µl of 2.2 × 10⁻⁴ M tetrodotoxin (TTX) dissolved in incubation medium into the cuvette (Calbiochem, final concentration 4 × 10⁻⁷ M) did not prevent the release of ATP by elevated extracellular K⁺ (increased by 47 mM). *c*, To chelate Ca²⁺, 10 µl of 250 mM EGTA (pH 7.4 with NaOH) were injected into the cuvette (final concentration of 4.7 mM EGTA). Removal of Ca²⁺ by EGTA reduced the maximal response to added ATP to about 57% of the control value but reduced the maximal response to increased extracellular KCl to about 21% of the control value.

shown to be Ca^{2+} -dependent¹³⁻¹⁶. In the present study, the presence of 4.7 mM EGTA to chelate Ca^{2+} seemed to reduce the release of ATP by elevated extracellular K^+ (Fig. 1c), but EGTA also reduced the sensitivity of the luciferin-luciferase system to added ATP. Closer examination shows, however, that EGTA reduced the maximum K^+ response to about 21% of the control value, whereas EGTA only reduced the sensitivity of the system to added ATP to about 57% of the control. It therefore seems that the release of ATP from synaptosomes by elevated extracellular K^+ is at least in part Ca^{2+} -dependent.

Injection of veratridine into a synaptosomal suspension caused a rapid release of ATP which could be prevented by the prior administration of tetrodotoxin (Fig. 2). Tetrodotoxin added at the peak of the veratridine response caused an abrupt fall in the observed release of ATP. These findings indicate that the release of ATP by veratridine, in contrast to that caused by elevated K^+ (see Fig. 1), was mediated by the opening of Na^+ channels. Surprisingly, veratridine produced a more prolonged release of ATP than did elevated K^+ . The nature of this prolonged release of ATP is currently under investigation.

This study clearly demonstrates a depolarisation-induced and possibly Ca^{2+} -dependent release of ATP from synaptosomal preparations. As to the origin of the ATP

released, it seems most likely that presynaptic nerve-terminals are involved, although it is also possible that glial contaminants of the synaptosomal preparation¹⁷ might respond to depolarising influences by releasing ATP. Elevated extracellular K^+ has been reported to release γ -aminobutyric acid from glial cells in dorsal root ganglia by a Ca^{2+} -dependent mechanism¹⁸. On the other hand, the veratridine-induced release of ATP from synaptosomal preparations indicates an involvement of Na^+ channels, which glial elements may not possess.

Whether or not the ATP is released in its own right or in conjunction with the release of neurotransmitters¹³⁻¹⁶ is not known. In either case, it does not seem reasonable that such an energetically valuable molecule as ATP would be released and hydrolysed simply to provide a source of adenosine to promote the post-synaptic synthesis of cyclic-3', 5' AMP (ref. 1). Perhaps the extracellular hydrolysis of released ATP provides energy for some functionally important process in the synaptic region.

Numerous other questions arise as to the nature, distribution and role of the ATP release process in brain. This new method for directly studying the depolarisation-induced release of ATP from synaptosomes may assist in answering these questions.

I thank Diana Webb for technical assistance. This work was supported by the MRC of Canada.

Fig. 2 Effect of veratridine on the release of ATP from synaptosomes. Synaptosomes were prepared and incubated as for Fig. 1. A stock solution of 27 mM veratridine (Aldrich) in ethanol was diluted 1:10 with incubation medium and 10 μ l of the latter solution were injected into the cuvette, giving a final concentration of 5×10^{-6} M veratridine. TTX in incubation medium was injected to give a final concentration of 4×10^{-7} M. Control injections of equivalent concentrations of ethanol did not promote chemiluminescence and a preliminary study showed that neither veratridine nor tetrodotoxin interfered with the response of the luciferin-luciferase system to added ATP.

Role of electrogenic sodium pump in slow synaptic inhibition is re-evaluated

THE mechanism of synaptic transmission at most synapses involves an increase in conductance of the postsynaptic membrane to certain ions^{1,2}. Certain slow postsynaptic inhibitions in both the central and peripheral nervous systems are, however, not generated in this way³⁻¹³. Nishi and Koketsu³⁻⁵ proposed that the slow inhibitory postsynaptic potential (IPSP) in bullfrog sympathetic ganglia is due to a unique mechanism, the synaptic activation of the electrogenic Na pump (see also refs 11-15). In many, if not all, neurones, the outward pumping of sodium is coupled to the inward transport of K, with more Na extruded than K taken in, thus producing an outward movement of positive charge¹⁶. This electrogenic pumping of Na, which is blocked by ouabain or K-free Ringer, produces a hyperpolarisation of the membrane without a change in membrane permeability¹⁶. In the present experiments, the direct role of the electrogenic Na pump in slow synaptic inhibition was tested. The experiments were carried out on the ninth or tenth paravertebral sympathetic ganglion of the bullfrog using the sucrose gap technique. We found that although electrogenic Na pumping was inhibited by

ouabain or K-free Ringer, the slow IPSP was not blocked by ouabain and was enhanced by K-free Ringer. The data are consistent with the hypothesis that the slow IPSP may result from an inactivation of Na conductance rather than from an activation of the electrogenic Na pump.

In mammalian sympathetic ganglia, the administration of nicotinic cholinergic agonists produces a brief depolarisation due to an increased conductance to Na^+ and K^+ . This is followed by an after-hyperpolarisation that results from the electrogenic extrusion of accumulated intracellular Na^+ ions¹⁷⁻¹⁹. We used this nicotinic after-hyperpolarisation to characterise the inhibition of electrogenic Na pumping in frog sympathetic ganglia by ouabain and K-free Ringer. Figure 1a (middle) shows that K-free Ringer rapidly inhibits the after-hyperpolarisation. This inhibition persisted as long as the preparation was bathed in K-free Ringer, but was rapidly reversible (Fig. 1a, bottom). Inhibition of the after-hyperpolarisation by ouabain occurred more slowly. Figure 1b (middle) shows that the after-hyperpolarisation following an acetylcholine (ACh) depolarisation was abolished after 1 h in ouabain 10^{-6} M. This effect was only slowly reversible, with the restoration of the ACh after-hyperpolarisation

Fig. 1 Effects of K-free Ringer and ouabain on electrogenic sodium pumping. *a*, Effect of K-free Ringer: *top*, control response of sympathetic ganglion to administration of ACh (3 mM) for 1 min (bar) (note rapid depolarisation due to increased Na and K conductance followed by more prolonged after-hyperpolarisation resulting from electrogenic pumping of Na); *middle*, response when superfusion with K-free Ringer (dotted line) started at peak of ACh depolarisation (note block of after-hyperpolarisation); *bottom*, recovery of the after-hyperpolarisation following an ACh depolarisation (recorded 25 min after return to normal Ringer solution). *b*, Effect of ouabain: *top*, control response to administration of ACh (2.5 mM) for 1 min (bar) (as in *a*, but from a different preparation); *middle*, response to ACh after superfusion for 1 h with Ringer solution containing ouabain (10^{-6} M) (note block of the after-hyperpolarisation); *bottom*, recovery of the after-hyperpolarisation following an ACh depolarisation, after washing with normal Ringer's solution for 4 h 45 min. All records from a rectilinear pen recorder (Brush Model 280). Experiments were carried out on the ninth or tenth paravertebral sympathetic ganglion of the bullfrog using sucrose gap recording⁴. The preparation was continuously perfused with oxygenated Ringer solution of the following composition (mM): NaCl 100, KCl 2, CaCl_2 1.8, Tris HCl 16, pH 7.2, and glucose 1 g l^{-1} . K-free Ringer had the same composition except that KCl was omitted.

Fig. 2 Effects of K-free Ringer and ouabain on the slow IPSP. *a*, Effect of K-free Ringer: *top*, control record of slow IPSP elicited by repetitive stimulation of the eighth spinal nerve with 1-ms pulses at a frequency of 50 Hz (2-s period of stimulation is indicated by the line labelled S under bottom record; nicotine $30 \mu\text{M}$ used throughout the experiment to antagonise the fast EPSP); *middle*, slow IPSPs recorded 30 and 50 min after beginning superfusion of ganglion with K-free Ringer (note increase in slow IPSP amplitude in K-free Ringer); *bottom*, recovery of slow IPSP recorded 25 min after return to normal Ringer; *b*, Effect of ouabain: *top*, control record of slow IPSP (as in *a* except from a different preparation; nicotine ($30 \mu\text{M}$) was used throughout the experiment to antagonise the fast EPSP); *middle*, slow IPSPs recorded 30 and 60 min after beginning superfusion with Ringer solution containing ouabain (10^{-6} M) (note small reduction in slow IPSP amplitude compared with control); *bottom*, slow IPSP after 20 min superfusion with K-free Ringer containing ouabain (10^{-6} M) (record taken after 90 min in ouabain (10^{-6} M), with 30 and 60 min records shown above; note increase in slow IPSP amplitude compared with 30- and 60-min records). Records from photographs of oscilloscope traces.

taking 4 h or more (Fig. 1b, bottom). These results indicate that K-free Ringer and ouabain are effective inhibitors of the electrogenic pumping of Na in the bullfrog sympathetic ganglion. We therefore used these agents to test the hypothesis that the slow IPSP is generated by the activation of the electrogenic Na pump.

Figure 2 illustrates the effects of K-free Ringer and ouabain on the slow IPSP. The application of K-free Ringer solution produced little or no change in resting membrane potential, but resulted in a rapid and persistent increase in the amplitude of the slow IPSP. Figure 2a illustrates the increase in slow IPSP amplitude after 30 and 50 min in K-free Ringer. To investigate the muscarinic slow IPSP, the nicotinic fast excitatory postsynaptic potential (EPSP) must be antagonised. When nicotine ($30 \mu\text{M}$) was used to antagonise the fast EPSP, 1 h in ouabain (10^{-6} M) resulted in a partial (10–40%) reduction in slow IPSP amplitude (Fig. 2b). When d-tubocurarine ($70 \mu\text{M}$) was used as the nicotinic antagonist, however, no significant reduction was observed after 1 h in ouabain (10^{-6} M). Figure 2b (bottom) shows that even after 90 min in ouabain, the administration of K-free Ringer still increased the amplitude of the slow IPSP.

Two hypotheses have been advanced to explain the electrogenesis of the slow IPSP. One proposes that the

slow IPSP is due to the activation of the electrogenic Na pump³⁻⁵. The present experiments show that although K-free Ringer and ouabain inhibit the electrogenic pumping of Na, they do not block the slow IPSP. The other hypothesis proposes that the slow IPSP is generated by a decrease in resting Na conductance⁷. This mechanism would readily explain the effects of ouabain and K-free Ringer in the present experiments. When the fast EPSP was antagonised by nicotine, the slow IPSP was partially reduced in amplitude after 1 h in ouabain. It is known that nicotine can increase resting Na conductance²⁰, and in the presence of ouabain, which inhibits the extrusion of Na⁺, an accumulation of intracellular Na would be expected¹⁹. This accumulation would decrease the Na gradient and thus reduce the amplitude of a slow IPSP generated by a decrease in resting sodium conductance^{2,7}. This interpretation is supported by the observation that when *d*-tubocurarine, a nicotinic antagonist that does not increase resting Na conductance²¹, was used, ouabain did not produce a significant reduction in slow IPSP amplitude. The enhancement of slow IPSP amplitude by K-free Ringer is difficult, if not impossible, to explain in terms of the electrogenic Na pump hypothesis, since the presence of extracellular K⁺ is necessary for the coupled extrusion of Na⁺ (ref. 16). On the other hand, such an enhancement is predicted by the inactivation of Na conductance hypothesis because the driving force for the slow IPSP is the K equilibrium potential, E_K (ref. 7), which would be increased in K-free Ringer, thus increasing the amplitude of the slow IPSP. Furthermore, if the slow IPSP were due to electrogenic Na pumping, the combination of ouabain and K-free Ringer would be expected to result in a greater reduction in slow IPSP amplitude. The observed enhancement (Fig. 2b), however, can be explained by the Na inactivation hypothesis, as discussed above. The present experiments suggest that the slow IPSP is not due to the synaptic activation of the electrogenic Na pump. On the other hand, the results can be readily explained by and support the hypothesis that the slow IPSP is generated by an inactivation of resting Na conductance.

The electrophysiological properties of the slow IPSP (ref. 7) are remarkably similar to both the hyperpolarising response of vertebrate photoreceptors to light²²⁻²⁴ and central neurones to noradrenaline⁸⁻¹⁰. The conductance decrease mechanism may therefore be of general significance in understanding the generation of slow inhibitions in the nervous system. Furthermore, this mechanism may have important functional consequences. In central neurones, such a hyperpolarisation of the membrane would inhibit neuronal discharge; the concomitant increase in membrane resistance, however, might be expected to increase the amplitude of convergent EPSPs (refs 25 and 26). This could result in an improved signal to noise ratio for convergent synaptic excitation.

Asymmetrical displacement currents in nerve cell membrane and effect of internal fluoride

WE have recorded asymmetrical displacement currents which may be linked to the activation of calcium permeability in the membrane of isolated snail neurones. The search for these currents was prompted by two lines of evidence. First, the existence of 'gating current' associated with sodium channel activity¹. And second, the existence of voltage-dependent charge movement in muscle fibres, which has some role in excitation-contraction coupling² and is supposedly involved in the process of calcium release³. An attempt to measure both Ca and Na gating currents in *Aplysia* neurones has been reported⁴.

We measured asymmetrical transients in neurones isolated from the snail *Helix pomatia*. The neurones were internally dialysed with potassium-free 130 mM Tris-phosphate solution +5 mM CsCl (pH 7.4). The external solution contained 120 mM Tris-HCl and 10 mM Ca and was free of Na, K and Mg. External cadmium ions were extremely effective in blocking

Fig. 1 Traces of calcium inward current (10₊, 10₋; left column) and corresponding asymmetrical transients (50₊, 50₋; right column). For the right column the Ca inward current was blocked by 2 mM Cd. The test potentials are indicated. Current calibrations were calculated for a single sweep. Holding potential -60 mV.

calcium inward current (K_d 7.2×10^{-5} M) (ref. 5). Therefore 2 mM CdCl_2 was added to the external solution to ensure complete and reversible block of the calcium current. All experiments were performed at 20–22 °C.

We used a modified version of the intracellular dialysis method described before⁶, including voltage clamp improvement, in this investigation. The main purpose of the modification was to increase the rate of the capacitive charging process. The isolated cell being fixed in the pore was impaled with a potential measuring microelectrode. This procedure minimised the error due to the series resistance. Further increase in the rate of response was achieved by a feedback technique suggested by Katz and Schwartz⁷, which gave better results than the conventional method of compensation for series resistance. Some experiments were performed without the additional feedback. The potential reached 95% of its final value in 150 μs with Katz and Schwartz compensation, in 350 μs with conventional compensation and in 1 ms with no additional feedback.

The calcium inward currents and asymmetrical transients were obtained in their net form after algebraic summation of membrane currents produced by an equal number of equal positive and negative voltage clamp pulses. Dwell time of the averaging was 50 μs . The number of pulses was usually 10 positive and 10 negative (10_+ , 10_-) for calcium currents and 50_+ , 50_- for asymmetrical transients. The interval between pulses was 1 s. In most cases positive and negative pulses were automatically alternated to ensure removal of slow inactivation. All kinds of symmetry tests were performed including averaging the pulses first from resting (-50 or -60 mV) and then from highly negative holding potential (between -100 and -150 mV). In the latter case negligible asymmetrical transients were obtained. The source of these transients has not yet been identified. They may be accounted for as the gating of fast potassium outward current, which is known to be inactivated with test pulses reaching -50 mV. The amount of charge transferred by the asymmetrical displacement current was calculated automatically by the averager which measured the area under the off-set line and then subtracted it from the area under the asymmetrical transient (for the 'on'-process) or subtracted the area under the asymmetrical transient from that under the base line (for the 'off'-process).

Fig. 2 *a*, Voltage dependence of charges Q_{on} (●) and Q_{off} (○) transferred by the displacement currents, calculated for a single sweep. *b*, Voltage dependence of Q_{on} (●) and calcium conductance g_{Ca} (○). Conductance was calculated for $V_{Ca} = 170$ mV (normalised). (Both *a* and *b* are from the same experiment as shown in Fig. 1).

Figure 1 shows a typical family of calcium inward current traces and corresponding asymmetrical transients obtained after cadmium block. The small inward current noticeable in the asymmetrical transient trace is due to rectification of the leakage current. The increase in test potentials above +20 mV led to the appearance of a time-dependent nonspecific outward current component. The presence of this component probably contaminated the asymmetrical transients at high test potentials by increasing the charge transferred during the 'off' pulse (Q_{off}). This is shown in Fig. 2*a* where the voltage dependence of Q_{on} and Q_{off} is presented. Q_{on} reached a peak and then tended to diminish, whereas Q_{off} persistently increased. Nevertheless, the equality of Q_{on} and Q_{off} at low test potentials allows us to identify the asymmetrical transients as displacement currents.

Figure 2*b* shows the voltage dependence of both g_{Ca} and Q_{on} . g_{Ca} was calculated as $I_{Ca}/(V - V_{Ca})$. To avoid the effect of the nonspecific outward current we obtained the reversal potential V_{Ca} from the instantaneous $I-V$ relationship at moderate test potentials. It varied between 130 and 200 mV

Fig. 3 *A*, The effect of fluoride on calcium inward current (*a-d*; V_t +8 mV; 10_+ , 10_-) and on the displacement current, with conventional compensation for series resistance. Averaging was performed first with Tris-phosphate inside (*a*), and then every 2 min after the application of fluoride (*b-d*). Sodium inward current (V_t -19 mV; 10_+ , 10_-) was observed after the return to normal Ringer (*e*). Holding potential -50 mV. *B*, The effect of fluoride on the displacement current. Record before (*a*) and after (*b*) adding fluoride. The feedback increasing the rate of response was introduced. Holding potential -50 mV. The negative off-set line in *b* is due to the decrease of outward going leakage current caused by internal fluoride. V_t +6 mV; 50_+ , 50_- .

for different cells. The value of V_{Ca} thus measured corresponds to that obtained for internally perfused barnacle muscle fibres⁸. g_{Ca} and Q_{on} have a similar potential dependence (Fig. 2b). This similarity, in fact, is not critically dependent on the V_{Ca} value. A decrease of Q_{on} and g_{Ca} at strong positive potential, although observed in the same potential region, could be only apparent: (1) the I_{Ca} values could be underestimated because of the nonspecific time-dependent current activation, and (2) a certain part of Q_{on} could be lost in the initial blank period because of the faster kinetics of the 'on'-process at more positive membrane potentials.

Like the calcium inward currents, the displacement currents were inactivated at more positive holding potentials. This inactivation was very pronounced, beginning with holding potential of -30 mV.

The substitution of internal phosphate by fluoride anions caused a complete and irreversible depression of asymmetrical displacement currents. It was accompanied by a decrease of outwardly directed leakage. Figure 3A demonstrates simultaneous reduction of the calcium inward current and of the initial displacement current. In this experiment the conventional compensation for series resistance was used. The delayed establishment of the final potential level led to the appearance of a rising phase in the time course of displacement current development. It is probable that the very slow rising phase of the calcium gating current described for *Aplysia* neurones⁴ is caused in a similar manner.

A small sodium inward current which was not blocked by fluoride could be detected in this cell after the return to normal Ringer (Fig. 3A). Its time course demonstrates that asymmetrical transients associated with sodium channel activation are completely lost in the 250- μ s blank period. Figure 3B shows a similar experiment but for displacement currents only and with the additional feedback.

Our data suggest that the selective block of calcium currents by internal fluoride is caused by irreversible damage to the gating mechanism of calcium channels.

We thank Professor C. F. Stevens for valuable discussions.

Does cyclic GMP mediate the negative inotropic effect of acetylcholine in the heart?

DURING vagal stimulation the pacemaker activity of the heart is diminished. The reduction in heart rate is due to a release of acetylcholine (ACh) from the parasympathetic nerve terminals that increases the permeability of the myocardial cell membrane for potassium ions (for review see ref. 1). This is accompanied by a shortening of the action potential duration in atrial muscle and a diminished calcium uptake², which in turn results in a negative inotropic effect. Voltage clamp experiments in mammalian atrial muscle have shown that with higher concentrations of ACh not only is the potassium current augmented but also the slow inward current of calcium is reduced³. It is

not clear how the current changes brought about by ACh are mediated. I have described the negative inotropic action of 8-bromo-cyclic GMP in the mammalian heart⁴, and these findings were confirmed in ventricular fibre fragments from mouse hearts⁵. If cyclic GMP levels in the myocardial cell are linked to the effects of ACh, as George *et al.* proposed⁶, then 8-bromo-cyclic GMP in addition to its negative inotropy should produce changes in the ion movements similar to those described for ACh. I report here the effects of 8-bromo-cyclic GMP on the action potential and the presumed underlying ion movements in rat atrial muscle.

Figure 1 shows the effects of 8-bromo-cyclic GMP on isometrically developed tension and on action potential configuration. Force of contraction was reduced to about 40% of control after 60 min; at the same time, the action potential duration was shortened at all voltage levels. Whereas the upstroke of the action potential is thought to be caused by an inflow of sodium ions⁷, the repolarisation phase is determined mainly by an outflow of potassium ions⁸. During the time course of repolarisation the potential is held at more positive potentials by an inwardly directed flow of calcium ions that has been reported for different species in ventricular and atrial preparations (for review see ref. 9). This slow inward current of calcium is believed to be of major importance for the initiation and maintenance of contraction^{10,11}.

The most direct way of testing any ion movements across cellular membranes is the use of radionuclides. Figure 2 shows that the calcium uptake in beating preparations was reduced in the presence of 8-bromo-cyclic GMP. The extent of the calcium inflow during the cardiac action potential could be diminished directly by a change in the conductance for this ion. Indirectly it could be diminished by a change in the currents of sodium and potassium that could either delay or prevent full activation of the calcium conductance by a decreased sodium inflow, or turn off and accelerate the inactivation of the calcium conductance by an increase in potassium outflow. The latter is thought to be true for low concentrations of ACh³. Either of these current changes would be detected by following the ion movements of sodium and potassium.

The uptake of radioactive sodium (²²Na, determined by liquid scintillation counting) or the net content of sodium (electrolyte contents were determined by atomic absorption spectrophotometry) were not altered in the presence of 8-bromo-cyclic GMP. Therefore the negative inotropic

Fig. 1 Effects of 10^{-4} M 8-bromo-cyclic GMP on isometric force (middle traces) and transmembrane action potential (other traces) in a rat left auricle after 60 min. The preparation was driven electrically at 0.2 Hz; other conditions were as described earlier⁴. The membrane potential was recorded intracellularly by the use of glass microelectrodes filled with 3 M KCl. C, control; G, 8-bromo-cyclic GMP.

Fig. 2 Effects of 10^{-4} M 8-bromo-cyclic GMP on ^{45}Ca uptake (a) and Ca net content (b) in resting or beating (2 Hz) rat left auricles. Hatched columns, control; filled columns 8-bromo-cyclic GMP. Radioactivity was determined by liquid scintillation spectrometry after the preparations had been dissolved in 0.5 ml of tissue solubiliser, and 1 ml of 1 N HCl, plus 10 ml of scintillation fluid, had been added. The ^{45}Ca space was calculated according to Grossman and Furchgott². Each column represents the means $\pm$ s.e. of eight preparations exposed for 15 min to ^{45}Ca after 30 min of stabilisation with or without 8-bromo-cyclic GMP. All values were obtained in individual preparations. The difference in ^{45}Ca uptake was not due to a change in the extracellular space (ECS, determined by the ^{14}C -inulin method, $n = 8$); also, the uptake of ^{45}Ca while at rest was not different in controls and preparations treated with 8-bromo-cyclic GMP, $n = 16$. The measurement of the transmembrane influx of calcium related to contraction is hindered by the influence of the extracellular space and the large amount of calcium taken up while at rest. These difficulties have been described by Grossman and Furchgott². The representation of resting uptake and extracellular space should demonstrate the large influence of these 'background values' on the measurements in beating preparations. Standard errors were omitted for clarity because these values were obtained in different preparations and not considered in the statistical evaluation of results. The net content of calcium was determined by atomic absorption spectrophotometry in 16 preparations, following the same time schedule and then ashing the preparations in a 1:1 mixture of HNO_3 : HClO_4 at 180°C and redissolving the ash in N/10 HCl solution containing 1% LaCl_3 .

action of 8-bromo-cyclic GMP does not seem to be accompanied by any change in sodium movements. Indeed, a change in ion fluxes was more expected with respect to potassium, because ACh is known to induce changes in the movements of this ion. Figure 3 shows, however, that potassium efflux did not change in the presence of 8-bromo-cyclic GMP; also, the net content of potassium was not significantly affected. The efflux curve of radioactive potassium in control muscles was virtually identical to that obtained in the presence of 8-bromo-cyclic GMP and was best fitted by the equation

$$\ln Y = \ln (100 - 0.031t)$$

In resting preparations, there was also no difference in the rate of efflux of ^{42}K with or without 8-bromo-cyclic GMP. The rate constant of potassium extrusion was slightly smaller than in beating preparations and amounted to $0.026 \pm 0.001 \text{ min}^{-1}$ (mean $\pm$ s.e., $n = 8$). In identical conditions, as described in the legend to Fig. 3, ACh increased the rate of potassium extrusion by a factor of about 1.3–1.4 (Fig. 4). Because maximally effective concentrations of both 8-bromo-cyclic GMP and ACh were used in the ^{42}K washout experiments, a quantitative difference in the cyclic nucleotide and acetylcholine sensitivity is unlikely.

Fig. 3 Effects of 10^{-4} M 8-bromo-cyclic GMP on ^{42}K efflux in rat left auricles electrically stimulated at 2 Hz. $\circ$, Control; $\bullet$, 8-bromo-cyclic GMP. Radioactivity was determined by liquid scintillation spectrometry and by γ -scintillation counting. Symbols represent means $\pm$ s.e. of six preparations each (the values including s.e. did not vary to a greater extent than the size of the symbols used). Control and test values were obtained in individual preparations that were loaded with ^{42}K for 90 min first; then, the amount of ^{42}K released by the muscle into non-radioactive Tyrode solution was determined each 5 min; after 60 min, the experiment was finished and the residual activity in the muscle was determined. The ^{42}K content of the muscle was calculated by cumulative addition of all released amounts of radioactivity for any time the ^{42}K effluent from the preparation had been determined. The theoretical curve (the equation is given in the text) was obtained from plots of log concentration against time, using the method of least squares.

The results show that the negative inotropic effect of 8-bromo-cyclic GMP can be explained solely on the basis of an alteration in the calcium influx in beating preparations. A corresponding change is seen in the configuration of the action potential. There is no indication that the potassium system is affected by 8-bromo-cyclic GMP in the way identified for ACh. Given that in voltage clamp experiments ACh also reduced the slow inward current of

Fig. 4 Effects of ACh on ^{42}K efflux in beating rat left auricles. $\circ$, Control; $\bullet$, 10^{-6} M ACh; $\blacksquare$, 5×10^{-6} M ACh. Experimental procedure was as described in Fig. 3. Means $\pm$ s.e. of rate constants of the washout process amounted to 0.028 ± 0.002 (control, $n = 4$), 0.036 ± 0.003 (10^{-6} M ACh, $n = 3$) and 0.038 ± 0.003 (5×10^{-6} M ACh, $n = 4$) min^{-1} . Correlation coefficients for all experiments varied between 0.996 and 0.999. Significance level for the difference between the washout curves obtained in control conditions and ACh was $P < 0.05$.

calcium in mammalian³ and frog^{12,13} atrial muscle, it is possible that the effects of ACh are mediated in part by changes in the intracellular levels of cyclic GMP; on the other hand, another pathway by which ACh mediates its physiological effects seems to be obvious.

I thank Barbara Elcombe and Barbara Schmelzle for help. The experiments depicted in Fig. 4 were suggested by the referee. This research was supported by a grant from the Deutsche Forschungsgemeinschaft.

Variation of thin filament length in heart muscle

ALTHOUGH the length dependence of force generation by heart muscle has been attributed to the degree of overlap of thin and thick filaments within the sarcomere, the required accurate values of the lengths of cardiac thin filaments have not been available. The existence in frog atrial trabeculae of thick filaments of uniform 1.55 μm length, of a small number of very long thin filaments, and of rosettes containing fewer or more than six thin filaments surrounding each thick filament has been noted¹ (Fig. 1), but no study of the dimensions of a statistically significant number of thin filaments has been made. Using serial transverse electron micrographs of cardiac cells we have found that the lengths of thin filaments vary by as much as 0.6 μm within a single sarcomere in a single myofibril. All other factors being constant, this broad range should increase the length of the plateau of the sarcomere length-tension relationship and allow the myocardial cells contracting *in situ* to operate entirely on the plateau. The sliding of

Fig. 1 Electron micrograph of a transverse section of rat atrial muscle. A small number of long thin filaments extends into the hexagonal M bridge and thick filament array. Thick filaments are surrounded by 0–6 thin filaments. Total magnification: $\times 121,000$.

Fig. 2 Relative frequency of thin filament lengths which are expressed in number of sections from the flat Z band for (a) rat atrial trabeculae, (b) frog atrial trabeculae, and (c) rat papillary muscle. The estimate of the section thicknesses was 0.1 μm whether it was based on the pale gold interference colour of the freshly cut, floating sections or derived from the known 1.5 μm length of the thick filament, which was used as an internal calibration standard that compensated for any generalised filament shrinkage⁶. The width of each histogram bar represents the section thickness and thus the limit of resolution of the technique.

myofilaments, therefore, should have little direct effect on force generation in the intact heart.

We have measured the lengths of populations of thin filaments in frog and rat atrial trabeculae and rat papillary muscle by analysing electron micrographs of serial transverse sections through a major portion of sarcomeres of muscles which were stretched and held throughout the preparative procedures of fixation and dehydration. Two different regions from each tissue were studied. Longitudinal sections are unsuitable for estimating filament length because in thick sections there is no discernible H zone, and in very thin sections there are the dangers of producing errors by either clipping off part of the filaments or superimposing filaments. To eliminate artifacts associated with the use of the approximately 0.1 μm thick transverse serial sections, regions were used only when the Z band was flat and entirely included within one section; when all filaments were absolutely perpendicular to the plane of section without using any tilting of the specimen stage; and when at least 400 thin and 200 thick filaments could be followed in a given region from one section to another. The numbers of thin and thick filaments were then counted in each transverse section and the relative lengths of thin filaments from the Z band deduced from the ratios of thin to thick filaments. Estimates of absolute values for filament lengths were determined by multiplying the number of serial sections through which the filaments extended by 0.1 μm , the approximate thickness of a section. Similar values were produced by using the length of the thick filament as an internal calibration. Values for the ratios of the number of thin to the number of thick filaments varied between 0 and 2. The maximum value of 2 attests to the suitability of the sarcomere for filament length analysis; a value greater than 2 would indicate poor lateral alignment of thick filaments, whereas a value less than 2 would show that some of the shortest thin filaments did not reach the A band

lattice as a result of overstretching of the muscle. Since the absolute number of thick filaments is constant throughout the A band, the relative numbers of thin filaments of each length have been obtained from a comparison of the ratios of thin to thick filament densities in each section. Typical data are shown in Fig. 2.

Thin filament lengths in frog atrial trabeculae varied from eight to more than thirteen section thicknesses, a span of more than $0.6\text{ }\mu\text{m}$, and in rat atrial trabeculae the range was equal to over six section thicknesses, or more than $0.6\text{ }\mu\text{m}$. In the rat papillary muscle, however, thin filaments differed in length from nine to more than eleven section thicknesses, or about half the spread of atrial tissue. The wide range of thin filament lengths found within a single sarcomere of a single myofibril indicates that there is no unique value for the extent of overlap even within one sarcomere. Consequently, any relation between length and force generation will be dependent not only on sarcomere length but also on the distribution of lengths of thin filaments.

An assessment of the effects of the broad distribution of lengths of thin filaments on the relationship between sarcomere length and developed force can be made if the data are coupled with the observations of Gordon *et al.*⁵, relating force to certain relative positions of thick and thin filaments. The calculations involved construction of sarcomere length-tension curves for each thin filament length, weighting by the appropriate factor from the length distribution, and summation of all the weighted curves to give a composite, calculated sarcomere length-developed tension curve. The exact basis for the corner between the ascending limb and the plateau has not been well defined;

the decrease in developed tension with sarcomere shortening past the plateau might be due to such things as interference of cross-bridge activity in the vicinity of a larger than usual number of actin filaments or the appearance of an internal resistance from the mutual interaction of thin filaments from opposite sides of the sarcomere during double overlap. Separate calculations based on decreased generation of force from either the sliding of a thin filament past the bare zone and into the opposite half of the A band or the double overlap of thin filaments from opposite sides of the sarcomere produced only slightly different results.

Figure 3a and b show the relations that were calculated using the first and simpler of the two modelling possibilities. The composite sarcomere length-developed tension curves of the atria have shapes distinctly different from that of skeletal muscle, particularly with respect to their much broader plateau regions. The wide range of thin filament lengths in atrial muscle provides a nearly constant degree of functionally effective thin and thick myofilament overlap over the physiological working range, and the sliding of filaments with changes in sarcomere length should therefore have little direct effect on the generation of tension.

The presence of a broad zone with only a very shallow slope in the length-tension relationship of calcium-activated, mechanically skinned cardiac fibres⁷ is consistent with the observed dimensions of thin filaments, and the absence of a plateau for the same relation in isolated cardiac muscles^{8,9} indicates that the modulation of force in the intact tissue must result from another step in the contractile cycle, such as activation⁷.

Of additional interest in this study was the correlation between the compliance of the tissue and the breadth of the distribution of thin filament lengths (Fig. 2); the stiffer papillary muscle had the narrower distribution. This raises the possibility that the breadth of the distribution may actually be set by the cell according to the amount of shortening which the cell undergoes in the intact heart to produce a plateau of adequate length in the sarcomere length-tension curve.

Sodium sensitivity of baroreceptors mediates reflex changes of blood pressure and urine flow

CARDIOVASCULAR baroreceptors are sensitive to vascular pressures and their input to the central nervous system is essential for the regulation of arterial blood pressure. They also contribute to the regulation of extracellular fluid volume, because their reflex effects upon arterial pressure and renal blood flow have marked consequences for urine flow^{1,2}. Since they are mechanoreceptors their properties may be affected by sodium and potassium ions³⁻⁵. Lowering extracellular Na^+ (Na_o^+) increases the threshold pressure at which arterial baroreceptors begin to discharge and reduces their sensitivity to suprathreshold pressures^{6,7}. We therefore investigated the reflex effects upon arterial blood pressure

Fig. 1 Effects of lowering extracellular Na^+ (Na_o^+) on baroreceptor discharge. *a*, The tall spikes in the top trace are the neural discharge of a single baroreceptor in control solution and the slowly rising line in the bottom trace is a pressure ramp of 20 mmHg s^{-1} . *b*, Same arrangement as (*a*) but the baroreceptor is now in $50\% \text{ Na}_o^+$ solution. The threshold pressure is clearly increased and maximum discharge frequency is reduced. *c*, Discharge frequency–pressure plot of the neural discharge shown in *a* and *b*. Each point on the frequency against pressure plot is the inverse period between two successive spikes. Filled circles (left hand curve) and filled rectangles (right hand curve) represent the neural discharge patterns shown in (*a*) and (*b*), respectively.

and urine flow elicited by lowering the Na_o^+ of carotid sinus baroreceptors. We report that reductions in Na_o^+ of as little as 5% increase arterial blood pressure and urine flow. We propose that the sodium sensitivity of baroreceptors is important for their function as regulators of arterial blood pressure and body fluid volume.

Figure 1*a, b* shows the pressure–discharge curves of a single rat aortic arch baroreceptor in control and $50\% \text{ Na}_o^+$ solution. Composition of the control solution was, in mM: Na^+ , 145; K^+ , 6; Cl^- , 127; Ca^{2+} , 1.1; Mg^{2+} , 1.2; HCO_3^- , 25; H_2PO_4^- , 1.2; SO_4^{2-} , 1.2; dextrose, 5.5. Na_o^+ was usually replaced by Tris [Tris (hydromethyl) aminomethane] at constant osmolality in the 95% and 87.5% Na_o^+ solutions and at a measured increase of less than 1% in the 75% Na_o^+ solutions and 2% or less in the 50% Na_o^+ solutions. Neural discharge was elicited by applying pressure ramps of $4\text{--}20 \text{ mmHg s}^{-1}$ to the aortic arch. Slow ramp rates such as these generate pressure–discharge curves which are very similar to those elicited by steady state pressure steps. Figure 1*c* shows the ‘instantaneous’ frequency versus pressure plots for the discharges and pressures shown in (*a*) and (*b*). Lowering Na_o^+ clearly increases the pressure for threshold discharge

and reduces the sensitivity to suprathreshold pressures. Seventeen individual baroreceptors studied in this manner showed similar responses to reductions in Na_o^+ of 25–50%.

The steady state pressure–volume relationship of the aortic segments used in these experiments was measured as described previously^{8,9}. The pressure–volume curves were unchanged by the test solutions so that the ionic actions were directly upon the receptors. In addition, the rate of rise of pressure in the isolated aortic segments elicited by fixed input ramp rates was unchanged in the test solutions.

The reflex experiments were performed on cats which had been in the vivarium for at least 2 d. They were fed Purina cat food and allowed to drink water freely. The animals were anaesthetised with a mixture of chloralose (Baker) 50 mg per kg body weight, and urethane (Matheson, Coleman & Bell), 200 mg per kg, injected intraperitoneally. The cervical vagi were cut bilaterally and one carotid sinus nerve was cut. The other carotid sinus was isolated and perfused via polyethylene tubing coupled to a Holter pump which was connected to a reservoir containing Krebs–Henseleit solution bubbled with 95% O_2 and 5% CO_2 and heated to 37°C . The perfusate was collected from the external carotid artery so that none

Fig. 2 Reflex effects of lowering Na_o^+ in the carotid sinus perfusate on arterial blood pressure and urine flow. *a*, Top trace is systemic arterial blood (mean arterial) pressure (MAP) and bottom trace is left carotid sinus pressure. Repetitive step increases in sinus pressure elicit repetitive falls in arterial pressure. As Na_o^+ in the carotid sinus is reduced at constant intrasinus pressure steps, mean arterial pressure rises and the oscillations in pressure elicited by constant steps are reduced. *b*, Mean arterial blood pressure as a function of carotid sinus Na_o^+ at constant mean carotid sinus pressure. Data are from nine animals. *c*, Plot of the % increase in urine volume over control as Na_o^+ is varied. The control urine flows were $39 \pm 0.003 \mu\text{l min}^{-1}$.

of it was added to the cat's circulating blood volume. Overdamped pressure steps could be superimposed by a parallel connection with a shaker pot (Ling 411) (Fig. 2a). Pressure in the perfusion circuit was measured using a Statham P23dB strain gauge manometer. Arterial blood pressure was measured by inserting a polyethylene catheter into a femoral artery. The catheter was connected to a Statham P23dB strain gauge manometer. The animal was given an intravenous injection of 0.9% NaCl equal in volume to 1.0% of body weight over 20 min at the beginning of the dissection. This was followed by continuous infusion of Krebs-Henseleit at 5 ml h^{-1} . Urine output was measured in timed fractions of 8–16 min duration by collecting the urine flowing from polyethylene catheters which were inserted into the ureters. Urine sodium concentration was measured using sodium glass miniature electrodes, or by an atomic absorption spectrophotometer (Instrumentation Laboratory IL253). The sodium glass was Corning NAS11-18, had a Nernstian response for Na^+ and a selectivity of 50:1 and 100:1 respectively over K^+ and NH_4^+ .

The isolated carotid sinus was perfused with the control solution until mean arterial blood pressure and urine flow became steady. This period was about 30 min. When the Na_o^+ in the sinus perfusate was lowered to 95% or 87.5% at constant mean sinus pressure of 90–100 mmHg, mean arterial blood pressure always increased (Fig. 2b) and urine flow was always enhanced (Fig. 2c). The changes in arterial blood pressure elicited by applying overdamped pressure steps to the isolated carotid sinus were also reduced in amplitude (Fig. 2a). The relationship between the Na_o^+ concentrations in the sinus perfusate and the changes from control of mean arterial blood pressure, and urine flow measured in nine animals, are shown in Fig. 2b and c. The increases in arterial pressure and urine flow evoked by the various test Na^+ solutions were statistically significant at the 0.01 level. Recovery of blood pressure and urine flow to control values occurred between each test solution. The test solutions did not change the distensibility of the common carotid artery or the isolated carotid sinus and we conclude, as we did for rat aortic baroreceptors, that the ionic effects are due to a direct action upon the baroreceptors.

The role of the renal sympathetic nerves in the diuresis was examined in another six animals. One kidney in each animal was denervated and urine flow and sodium excretion were compared between the innervated and denervated kidneys of the same animal. Denervation did not affect control arterial blood pressure; a small but not significant increase in urine flow did occur¹⁰ (Fig. 3). Na^+ excretion which varied considerably was reduced but the change was not significant (Fig. 3). Lowering Na_o^+ to 87.5% in the isolated sinus always increased arterial blood pressure and urine flow and the increases were statistically significant. The diuresis was not different, however, between the innervated and denervated kidneys. Sodium excretion was not altered significantly by the test sinus solutions (Fig. 3).

The action of reduced Na_o^+ upon the carotid sinus baroreceptors is not due to an osmotic effect since the osmotic pressure was unchanged by Tris substitution for Na_o^+ at the 5% and 12½% levels and only slightly increased at 25% and 50% levels. Nor is the effect likely to be related to an action of Tris since replacement of 5% or 12½% NaCl with isosmotic sucrose (four experiments) gave the same response as substituting Tris for Na^+ . It is possible that lowering Na_o^+ inhibited carotid body afferent discharge. The reflex effects on blood pressure would tend to offset the reflex effects of reducing baroreceptor input so that the sodium sensitivity of the baroreceptor reflexes might be even greater than the present experiments

Fig. 3 Comparison between innervated and denervated kidneys of the effects of lowering carotid sinus Na_o^+ . *a*, The urine volumes are compared for innervated and denervated kidneys from six animals when the isolated carotid sinus was perfused with control solution, C, and when it was perfused with 7/8 Na_o^+ . There was a significant difference ($P < 0.01$) between the effects of control solution and 7/8 Na^+ upon urine flow in both kidneys but there was no significant difference between innervated and denervated kidneys. *b*, The total urinary sodium output when the sinus is perfused with control and 7/8 Na^+ . Six animals were compared in this way. There were no significant differences between the effects of the two solutions on innervated or denervated kidneys.

indicate.

The sensitivity to Na_o^+ was greater in the reflex experiments than in the individual baroreceptor discharge experiments⁷. This is undoubtedly due to the fact that in the reflex experiments all of the baroreceptors are tested simultaneously. The experiments using individual baroreceptors are complicated by the variability in threshold and sensitivity among different receptors as well as a 1–2% variability in individual receptors.

Arterial baroreceptors respond to small decreases in extracellular Na^+ concentration by producing a reflex increase in arterial blood pressure and urine flow. Sodium excretion seems to be unchanged but, because of its variability, this point is not definitely established. The mechanism of the diuresis is unclear. The renal nerves do not seem to be essential and changes in antidiuretic hormone (ADH) secretion are unlikely to be involved since ADH is increased by reductions in baroreceptor discharge¹¹. The increase in arterial blood pressure is a likely possibility¹². Sodium sensitivity of baroreceptors may be an important mechanism for prompt regulation of body fluid volume, and ionic sensitivity of cardiovascular baroreceptors is possibly as important to body function as their pressure sensitivity.

Interaction of DNA and liposomes as a model for membrane-mediated DNA damage

We have described the antioxidant activity of calf thymus DNA on the oxidation of liposomal suspensions¹; we now report the damaging consequences to the biological activity of bacterial transforming DNA in such a system. Because DNA is associated with eukaryotic² and bacterial cell membranes³, the DNA-membrane interaction described here may be relevant to several pathological processes, including carcinogenesis⁴⁻⁷, ageing⁸⁻¹¹ and oxygen-dependent, radiation-induced cell lethality^{10,11}. In the presence of oxygen, the unsaturated fatty chains of membrane phospholipid undergo autoxidation¹². These autocatalytic free radical reactions, due to their chain nature, both amplify and propagate an initiating event occurring within the membrane, during which time many highly reactive and potentially damaging chemical species are formed¹³.

In view of the previous findings, we decided to investigate the possibility that retardation by DNA of the oxidative free radical reactions occurring within membrane phospholipids¹ would damage the DNA. Incubation mixtures of liposomes and *Bacillus subtilis* or calf thymus DNA were studied. Because liposomes are highly organised bilayers, they provide a model of *in vivo* membrane phospholipid configuration¹. The content of polyunsaturated fats was increased by enrichment with methyl arachidonate to enhance the rate of lipid oxidation in the bilayer system¹. Lipid oxidation was monitored colorimetrically by the thiobarbituric acid method (A_{532}) and spectroscopically by diene conjugation ($A_{233/215}$). DNA damage was assayed by measuring the reduction in transforming activity of *B. subtilis* BD 170 (thr 5 trp 2) cells. Figure 1 shows the effect of various concentrations of calf thymus DNA on the oxidation kinetics of methyl arachidonate-enriched phosphatidyl choline liposomes (PCMA)¹. None of the DNA concentrations studied increased the induction period, which in this experiment was approximately 21 h. The DNA did, however, retard the rate of lipid oxidation in a concentration-dependent manner. This and other results (ref. 14 and personal communication from K. M. Schaich and D. C. Borg) suggest that DNA interacts with the oxidising model membrane system as a free radical acceptor or trapping agent^{1,13}. Figure 2 shows the lipid oxidation kinetics of phosphatidylcholine (PC) and PCMA liposomal suspensions containing *B. subtilis* transforming DNA ($4.5 \mu\text{g ml}^{-1}$). The fatty chain profile, buoyant density characteristics and oxidation kinetics of these liposomes have been described before¹. The induction period for each suspension is the same, although the PCMA liposomes oxidise at a greater rate because of their higher degree of polyunsaturation. At the times indicated by the arrows in Fig. 2, DNA was isolated from each suspension and assayed for transforming activity (Table 1). DNA incubated in either sodium phosphate buffer or standard saline citrate (SSC) was stable during 68 h incubation, but DNA incubated with the oxidising liposomal suspensions lost its transforming activity in a manner dependent on the magnitude of lipid oxidation which has occurred in each suspension up to the time of sampling. In this respect, PCMA liposomes decreased the transforming activity of DNA by a factor of 2 during 16 h incubation, while the more slowly oxidising PC liposomes

caused no DNA damage. By 36 h incubation, PCMA liposomes had caused DNA transforming activity to decrease by a factor of 3,000 (the limit of the system), while PC liposomes had caused it to decrease by a factor of 8, again reflecting their lower oxidation rate relative to PCMA liposomes. After incubation with DNA for 68 h, PC liposomes also caused the largest detectable decrease in DNA transforming activity, by a factor of 3,000.

We also incubated *B. subtilis* DNA with PC and PCMA liposomes in SSC. During 68 h incubation, neither PC or PCMA underwent autoxidation, and accordingly DNA incubated in these non-oxidising systems retained its full transforming activity throughout the 68 h. Furthermore, fully saturated dipalmitoyl phosphatidyl choline liposomes suspended in sodium phosphate buffer underwent no autoxidation during 68 h incubation at 45 °C, and, correspondingly, *B. subtilis* DNA retained full transforming activity when incubated with these suspensions during that time. These controls show that non-oxidising membrane lipid *per se* has no effect on the transforming activity of DNA; for damage to occur, the lipids must be oxidising.

Taken together, these results indicate that oxidation of highly organised lipid bilayers can damage DNA. The species of oxidising lipid responsible for this damage are unknown but could be free radicals or reactive non-radical compounds. Free radicals, such as the $\cdot\text{OH}$ radical, which are produced during lipid autoxidation, have been shown to damage DNA¹⁵. The finding that DNA acts as a radical trapper in the model systems described before would support the hypothesis that DNA damage is caused, at least

Fig. 1 Oxidation kinetics of PCMA liposomal suspensions containing various concentrations of calf thymus DNA. PCMA liposomes were incubated alone or with various concentrations of dialysed calf thymus DNA in 0.05 M sodium phosphate buffer pH 7.5, as previously described¹. Total lipid concentration was 10 mM. Lipid oxidation was monitored by both A_{532} and $A_{233/215}$. Each point plotted represents the average of readings taken from two identically prepared liposomal incubation samples during a typical experiment. These results have been repeated three times. ●, PCMA; □, PCMA+DNA ($4.5 \mu\text{g ml}^{-1}$); ▲, PCMA+DNA ($45 \mu\text{g ml}^{-1}$); △, PCMA+DNA 225 ($\mu\text{g ml}^{-1}$).

Fig. 2 Oxidation kinetics of PCMA and PC liposomal suspensions each containing *B. subtilis* DNA. PCMA and PC liposomes were incubated with *B. subtilis* ^3H -DNA ($4.5 \mu\text{g ml}^{-1}$) in 0.05 M sodium phosphate buffer pH 7.5, as described for PCMA liposomes and calf thymus DNA¹. Transforming ^3H -DNA (specific activity 2,000 d.p.m. μg^{-1}) was isolated from *B. subtilis* BD 204 (his B2 thy) (given by D. Dubnau) grown for four generations in SPI medium²⁹ containing L-histidine hydrochloride hydrate ($50 \mu\text{g ml}^{-1}$), thymidine ($1.5 \mu\text{g ml}^{-1}$) and $1.75 \mu\text{Ci } ^3\text{H}$ -thymidine ml^{-1} (19 Ci mmol^{-1}) by the Sepharose 4B procedure³⁰. Total lipid concentration was 10 mM in each suspension. Both A_{532} and $A_{233/215}$ were assayed to monitor lipid oxidation. Each point plotted is the average for four independent samples. The arrows indicate the times when samples were assayed for DNA transforming ability. ●, ▲, PCMA+DNA; ○, △, PC+DNA.

in part, by this radical attack. The carbonyl malondialdehyde is a typical non-radical, reactive compound formed during lipid peroxidation¹³. Malondialdehyde binds to DNA, decreasing its ability to serve as a template for RNA polymerase¹⁶. While unorganised emulsions of oxidising polyunsaturated fatty chains have been shown to damage DNA in conditions that enhance such carbonyl-DNA interaction (pH 4.6)¹⁷, the defined structural ordering in the membrane models used in the study reported here as well as the difference in pH between it and the previous work¹⁷, would make extrapolation difficult.

It has been suggested that membranes are the site of oxygen enhancement of radiation-induced cell lethality (the so-called "oxygen effect")^{10,11}. Supporting evidence includes

Table 1 Transforming activity of *B. subtilis* DNA after incubation with PC or PCMA liposomes

Incubation time (h)	DNA	Sample incubated DNA+PC	DNA+PCMA
0	3,250	3,320	2,850
16	2,690	3,105	1,471
36	3,190	427	0
68	3,030	0	0

At the times indicated by the arrows in Fig. 2 and listed above, a 0.5-ml sample was removed from each incubation sample, added to 10 ml cold absolute ethanol and centrifuged at 15,000 r.p.m. for 20 min at 4 °C. The resulting BD204 ^3H -DNA pellet was resuspended in 0.5 ml sodium phosphate buffer, pH 7.5. After 0.1 ml was counted to determine the ^3H -DNA concentrations, a volume corresponding to $0.45 \mu\text{g}$ of ^3H -DNA (0.15 ml) was assayed for ability to transform BD170 (thr 5 trp 2) to threonine independence²⁷. Transforming activity is the number of BD170 cells transformed by $0.45 \mu\text{g}$ of BD204 ^3H -DNA per 5×10^7 exposed cells. Incubation samples consisted of BD204 ^3H -DNA ($4.5 \mu\text{g ml}^{-1}$) alone in either 0.05 M sodium phosphate buffer, pH 7.5, or 0.015 M NaCl and 0.0015 M sodium citrate (SSC), pH 7.0, (DNA); or mixed suspensions of BD204 ^3H -DNA ($4.5 \mu\text{g ml}^{-1}$) with 10 mM PCMA (DNA+PCMA) or 10 mM PC (DNA+PC) in 0.05 M sodium phosphate buffer, pH 7.5, as shown in Fig. 2. Each value is the average for four independent samples. The standard deviation for each value is $\leq 10\%$.

the effects of lipid-soluble inert gases¹⁸, the "time resolved O_2 effect"¹⁹, and the large O_2 effect on DNA-membrane complexes²⁰. In addition, ionising radiation initiates the oxidation of ordered micellar fatty chains with a G value of approximately 100 (ref. 21). Hence the type of membrane-mediated DNA damage described here is a possible mechanism of the O_2 effect, and the markedly higher solubility of oxygen in lipid, compared with water, makes this suggestion even more attractive²².

The relevance of this type of interaction in carcinogenesis is supported by the findings that both lipid peroxides and malondialdehyde are mutagenic^{23,24} and carcinogenic^{23,25}. Therefore, the components necessary to produce carcinogenic insult, that is O_2 and unsaturated fatty chains, are present in all cells in normal conditions. It has been proposed that lipid autooxidation is a continual process in living aerobic cells, and is restrained from entering the autocatalytic phase by enzymes and antioxidants⁸. Chemical and physical agents which enhance membrane free radical reactions may accelerate this process beyond the capabilities of those restraining systems and result in widespread membrane lipid oxidation and cell death^{13,26}.

Finally, it has been hypothesised that one cause of cellular ageing is membrane lipid oxidation-mediated damage to DNA and other macromolecules⁸. The studies described here demonstrate that oxidising membrane lipids impair the biological function of DNA and support this view.

The importance of the interaction of oxidising membrane lipids with DNA and/or other critical biomolecules in various pathological conditions can now be studied more directly using the unsaturated fatty acid-requiring auxotrophs isolated from *E. coli*²⁷ and Chinese hamster ovary²⁸ cell lines.

Gap filling during postreplication repair of DNA in recombination deficient *Escherichia coli*

POSTREPLICATION repair of DNA is one pathway for repair of damage inflicted on DNA by physical and chemical agents in the environment¹. Postreplication repair can involve error-prone repair of pyrimidine dimers in *Escherichia coli*², and as such may be particularly relevant to the understanding of the alteration of initial damage in DNA to a transformed or mutant DNA. The assignment of gene products to essential roles for completion of postreplication repair gap filling after ultraviolet light (UV) damage in *E. coli* cells³⁻⁷ has been complemented by consideration of their respective roles in error-prone repair of UV damage⁸⁻¹¹. We have used column chromatography, which separates double-stranded DNA containing single regions from completely double-stranded DNA, to observe the gap filling during postreplication repair of UV damage to DNA. In addition, analysis of *E. coli* *recA* or *lex* mutants demonstrated that the *recA*⁺ or the *lex*⁺ gene products must control steps exclusive of the initial gap filling process during postreplication repair.

DNA synthesised immediately after exposure to UV is discontinuous¹². Closure of these daughter strand gaps can be demonstrated by analysis of alkaline sucrose density gradient profiles. DNA increases in size (filling and joining) with reincubation. Alkaline sucrose centrifugation analysis of DNA size, however, does not differentiate the initial steps in gap filling from partially completed gap filling. In contrast, benzoylated naphthoylated DEAE-cellulose (BN-cellulose) chromatography is sensitive to the single-stranded regions in the double-stranded DNA structure and thus is suitable for analysis of the progress of gap filling. BN-cellulose chromatography was used successfully by Iyer and Rupp¹³ to measure the average gap size generated by DNA synthesis on UV-damaged parental DNA. We have used the same procedure.

E. coli cells were grown, exposed to UV and labelled with ³H-thymidine, and DNA was released and sheared as described by Iyer and Rupp¹³. Caffeine elutions from the BN-cellulose column of DNA from AB3063 cells with and without UV exposure were duplications of the procedure of Iyer and Rupp and gave the same results for the same strain. The work described here had an additional step, whereby some cells were reincubated in non-radioactive medium before caffeine elution. In addition, strains deficient in *recA*⁺ gene product were studied. The same procedure was used for a strain deficient in *lex*⁺ gene product and for its progenitor. The results shown here represent means of three to seven experiments with standard errors of the mean given for the caffeine elution.

In *E. coli*, the *recA*⁺ gene product controls postreplication repair. DNA from *recA* mutant cells that have been reincubated for 60 min after UV treatment does not increase to the size of DNA from unirradiated cells³. DNA from *E. coli* *lex* mutants demonstrates a slow increase in DNA size in the same conditions⁴. The results for postreplication repair observed indirectly by BN-cellulose chromatography in this study agreed with those of alkaline sucrose centrifugation studies: a protocol producing postreplication repair of daughter strand gaps in *recA*⁺*lex*⁺ cells as indicated by gradient profile analysis resulted in a commensurate decrease in the number of daughter strand gaps indicated by BN-cellulose chromatography (Table 1). Analysis of BN-cellulose chromatography elution, however, demonstrated that *recA* or *lex* mutant strains, which are slow or unable to complete postreplication repair, were able to convert DNA with single-stranded regions to double-stranded DNA (Table 1). These experiments were repeated with additional *recA* strains including a *recA56recB21recC22* strain and isogenic *recA* and *recA*⁺ strains obtained from Dr S. D. Barbour (not shown), and the results indicated that wild type cells and mutants could convert equal amounts of gapped DNA to double-stranded DNA. Thus, while *recA*⁺ and *lex*⁺ gene products are essential for normal levels of postreplication repair, mutants demonstrate extensive conversion of UV-induced postreplication daughter strand gaps to double-stranded DNA.

Howard-Flanders¹ and Hanawalt¹⁴ have reviewed the possible mechanisms of postreplication gap filling. They discussed the roles, relative to the gap filling process, of *de novo* DNA synthesis, DNA strand exchange and the process by which gap filling is initiated. Our results support the hypothesis that the *lex*⁺ and *recA*⁺ gene products in wild type cells are essential for postreplication repair gap closure after initiation of gap filling and/or the first steps thereof. Essentially, the function of the error-prone repair *recA*⁺ or *lex*⁺ gene product seems to be the filling of the minority of the gap.

An alternate explanation for the gap filling observed in *E. coli* *recA* or *lex* mutants could involve preferential degradation of the single-stranded parental DNA forming the gap backbone. Although the stability of the parental DNA was not measured in the experiments shown here, degradation might be below detectable levels even if the parental DNA were labelled. Nevertheless, such degradation would precipitously decrease the size of parental DNA as measured with alkaline sucrose gradient analysis during post-UV reincubation of *recA* mutants. This has not been observed in gradient analysis in this laboratory. More importantly, in the *recArecBrecC* mutants, with greatly reduced degradation ability, loss of daughter strand gaps was observed as with the *recA* mutant (not shown).

An alternative hypothesis is that gap filling represents the function of proteins produced by leaky mutants. If, however, the *recA*⁺ gene product were responsible for the control of all the steps

Table 1 Step elution from BN-cellulose of ³H counts from preparations of irradiated or unirradiated *E. coli*

in gap filling in leaky mutants, a 60 min reincubation should permit significant gap closure, measurable on alkaline sucrose gradients, which is not observed³.

Studies by Witkin⁹ and others suggest that some *E. coli recA* mutant cells can survive low doses of UV but are differentially repaired with less error than *recA*⁺ survivors. Presumably some completed gap filling occurs after a 24 h reincubation⁹. The identity of proteins responsible for this completion of gap filling or final closure and the fate of the pyrimidine dimer during error-prone repair are now under investigation in this laboratory.

This research was supported by the NCI. I thank Dr S. R. Moses, J. Karam, L. Chao, W. D. Rupp and T. Higerd for helpful discussions and criticisms. I also thank Dr Kushner for helpful discussions about the *recArecBrecC* strain, and E. Terry for technical assistance and Charles L. Smith for editorial assistance.

Repair of DNA damaged by alkylating carcinogens is defective in xeroderma pigmentosum-derived fibroblasts

THE human hereditary skin disease xeroderma pigmentosum (XP) is characterised by extreme sensitivity to sunlight and a high incidence of sunlight-induced skin cancer. These symptoms seem to be correlated with a defect in the excision repair of ultraviolet-induced dimers¹. Repair of DNA damage caused by chemical carcinogens belonging to the group of monofunctional alkylating agents was thought to be normal in XP cells, however, because after treatment with these agents the amounts of repair replication^{2,3} and the numbers of chromosome aberrations⁴ were similar in normal and XP cells. Contrary to this indirect evidence, it is reported here that direct measurement of the amounts of two products formed by alkylating carcinogens in the DNA and of the rate at which they are eliminated indicates that XP cells have a defect in this type of repair also.

XP-derived fibroblasts and normal human fibroblasts were treated with the potent carcinogens *N*-methyl-*N*-nitrosourea (MNU) and *N*-ethyl-*N*-nitrosourea (ENU). From the alkylation products formed, only the amounts of 7-alkylguanine and *O*⁶-alkylguanine were measured—7-alkylguanine because it is a major product and indicates the overall reactivity of the carcinogen with nucleophilic centres in the DNA and *O*⁶-alkylguanine because it seems to be critical for the mutagenic and carcinogenic action of alkylating agents⁵⁻⁹. *O*⁶-alkylguanine has been shown to cause mis-coding and anomalous base pairing⁵, and the relative amounts of this base that are produced by different agents seem to correspond to their carcinogenic potency⁶. In addition, the inability of an organ to excise *O*⁶-alkylguanine enzymatically from its DNA correlates with the organ-specific carcinogenic action of alkylating agents⁷⁻⁹.

Human fibroblasts from a normal donor (GM637) and from an XP patient of complementation group A (XP12RO) were treated with 8.7 $\mu\text{g ml}^{-1}$ ³H-MNU or 100 $\mu\text{g ml}^{-1}$ 1-¹⁴C-ENU for 45 min. The DNA was isolated 0, 24 and 48 h after the treatment and, after DNA hydrolysis, the purine bases were separated by Sephadex G10 chromatography (see Table 1 and ref. 10). The amount of each alkylguanine was determined from the radioactivity eluted in the position of the appropriate marker and was expressed as a fraction of the total guanine.

Normal and XP cells had about the same amounts of alkylated guanine immediately after treatment with an alkylating agent (Table 1), and the relative yields of *O*⁶-alkylguanine and 7-alkylguanine corresponded to those found *in vivo* in the rat^{10,11} and *in vitro* after reaction of DNA with MNU or ENU (refs 6, 10). The loss of 7-alkylguanine from DNA was similar in both cell lines, but there was a significant difference in the loss of *O*⁶-alkylguanine. Whereas in normal cells *O*⁶-alkylguanine was reduced to 28% of the initial amount 48 h after MNU treatment and to 9% 48 h after ENU treatment, there were still 63% (MNU) and 70% (ENU) of the initial *O*⁶-alkylguanine in XP cells at this time.

These reductions of alkylguanines partly reflect dilution by cell proliferation because the amount of alkylguanine is expressed as a fraction of the total guanine. To exclude this dilution effect and to eliminate differences in the rate of cell proliferation between cell lines, *O*⁶-alkylguanine was expressed as a fraction of 7-alkylguanine (Fig. 1). In normal cells this ratio decreased to one-third of the initial value 48 h after treatment with ENU and stayed constant after treatment with MNU, indicating the *O*⁶-alkylguanine was lost from the DNA as fast as or faster than 7-alkylguanine. In XP cells, however, the ratio of the two agents about doubled during the 48 h for both ENU- and MNU-treated cells, which means that 7-alkylguanine was lost much faster than *O*⁶-alkylguanine in these cells.

The reason for the similar rates of loss of 7-alkylguanine in normal and XP cells but the very different rates of loss of *O*⁶-alkylguanine may involve different mechanisms for removing the two bases. Alkylation of guanine at the N7 position labilises the *N*-glycosidic bond and leads to non-enzymic depurination of the base¹². A mechanism of 7-alkylguanine loss based on spontaneous depurination and dilution by cell proliferation predicts that similar rates of loss would occur in cells that have similar division rates. This was the case in normal and XP cells (Table 1), although enzymic excision cannot be excluded. *O*⁶-alkyl-

Fig. 1 Ratio of *O*⁶-alkylguanine to 7-alkylguanine in the DNA of normal human fibroblasts (---) and XP fibroblasts (—) after treatment with methylnitrosourea (○) or ethylnitrosourea (▲) as a function of time.

Table 1 Amount of alkylated guanine in the DNA of normal and xeroderma pigmentosum fibroblasts after treatment of the cells with ^3H -methylnitrosourea or $1\text{-}^{14}\text{C}$ -ethylnitrosourea as a function of time

Cell lines, which had been transformed by SV40 virus, were chosen because of their high rate of cell division. Previous studies have demonstrated that transformation does not alter DNA repair characteristics of human fibroblasts^{21,22}. The cells were grown in Eagle's minimum essential medium with 10% calf serum in 1-gallon roller bottles. For one alkylation experiment cells from four confluent cultures were trypsinised and resuspended in 25 ml of serum-free Eagle's minimum essential medium in a Spinner flask and stirred at 37 °C at a speed that kept cells in suspension. The alkylating agent was then added— $8.7 \mu\text{g ml}^{-1}$ ^3H -MNU ($123.2 \text{ Ci mol}^{-1}$, 0.87 mg ml^{-1} in ethanol) or $100 \mu\text{g ml}^{-1}$ $1\text{-}^{14}\text{C}$ -ENU (4.98 Ci mol^{-1} , dissolved just before use in citric acid-disodium phosphate buffer, pH 6)—and the cells were incubated for 45 min. DNA from one-third of the cells was isolated immediately. The rest of the cells were put back into roller bottles and grown for 24 or 48 h before collection by trypsinisation. Cells were lysed in 0.1% sodium dodecylsulphate in SSC (0.15 M sodium chloride + 0.015 sodium citrate) and then incubated first with RNase (final concentration 0.1 mg ml^{-1}) for 1 h and then with pronase (final concentration 1 mg ml^{-1}) for 2 h at 37 °C. The DNA was precipitated by 2 volumes of ethanol and hydrolysed in 0.1 N HCl (37 °C, 20 h); the purine bases were separated by chromatography on a Sephadex G10 column ($80 \times 1.5 \text{ cm}$) eluted with 0.05 M ammonium formate (pH 6.8). The amount of each alkylated guanine was calculated from the specific radioactivity of the given alkylating agent and the integral radioactivity of the chromatographic peak corresponding to a marker for the appropriate alkylated base, and was expressed as a fraction of the total guanine in the isolated DNA, which was determined from the absorbance of the guanine fractions from the column eluates. For details see ref. 10.

guanine, on the other hand, is chemically stable in DNA^{10,13} and must be enzymically excised. Because the XP cells under investigation lost much less O^6 -alkylguanine than normal cells did, this loss might have been completely due to dilution by proliferation rather than to excision.

Although the doses of MNU and ENU used in this experiment produced almost the same amount of O^6 -alkylguanine, the observed excision from the DNA of normal cells was much faster after ENU treatment than after MNU treatment (Table 1, Fig. 1). This might imply that the ethylated derivative is excised more efficiently. But, MNU also produced much higher overall alkylation in the cell, the alkylation at the N7 position of guanine being, at the doses used, about six times higher than with ENU, so a similarly higher reaction with proteins can be expected. Thus, a reasonable explanation for the slower excision of O^6 -methylguanine is that enzymes of the repair system are partially inactivated by the MNU dose used.

Though it has been shown that O^6 -alkylguanine is excised enzymically in mammalian cells, it is not yet known if the enzyme is of the nucleotidase type or of the N-glycosidase type¹⁴. The enzyme that excises O^6 -alkylguanine in *Escherichia coli*, endonuclease II¹⁵, seems to be an N-glycosidase that works in conjunction with an apurinic endonuclease¹⁶. If the same mechanism is at work in mammalian cells, then XP cells of complementation groups A and D may have a defect in the entire repair process, because it has already been shown that there is a defect in their apurinic endonuclease activity¹⁷.

This type of repair seems to have an important role in carcinogenesis. It has been shown that the rate at which O^6 -alkylguanine is excised varies greatly in different rat tissues, being fastest in liver, intermediate in kidney, and very slow in brain⁷⁻⁹. As MNU and ENU are both nervous-system-specific carcinogens in the rat¹⁸, the inability of the brain to excise this potentially mutagenic damage correlates with the organ-specific carcinogenic action of these agents. The inability of XP-derived fibroblasts to excise this damage might not be representative of all XP-derived cell types, although it seems unlikely that the inheritable change connected with this disease would be expressed in only one cell type.

It has recently been reported that, unlike the number of chromosome aberrations, the frequency of sister chromatid exchanges is much higher in XP cells than in normal cells

after treatment with alkylating agents¹⁹. This raises the question of whether there is a causal relation between the unexcised O^6 -alkylguanine and the increased sister chromatid exchange.

Because measurements of repair replication by isopycnic analysis and by autoradiography after treatment with alkylating agents do not show a difference in repair by normal and XP cells^{2,3}, these techniques do not seem applicable when various types of damage occur. It especially does not seem to be an accurate measure of excision, because the main product, 7-alkylguanine, depurinates spontaneously. Also, although almost no repair is detectable by this technique 20 h after ENU treatment of normal cells²⁰, the work described here shows that more than 50% of the alkylated bases are still present in their DNA.

I thank G. Thomas for technical help, Drs R. B. Painter and S. Wolff for helpful discussions and Dr J. E. Cleaver, who suggested the experiments. This work was supported by Deutsche Forschungsgemeinschaft and US ERDA.

The Science Dictionaries

Three useful and up-to-date works of reference intended not only for students, teachers and researchers but also for science journalists and the general reader.

Each book is designed for easy use – entries are arranged alphabetically and defined under the most common form of term, with synonyms in brackets. S.I. units are used throughout and all entries are thoroughly cross-referenced.

A Dictionary of Life Sciences

E. A. Martin

The recent trend to treat the biological/life sciences as a whole rather than divided into separate units is reflected in this concise dictionary which brings together in one volume all the main branches of zoology and botany. Selected terms in related fields of biochemistry, endocrinology, animal behaviour and palaeontology are also included. All major plant and animal classes are fully described as well as the more important orders, and common names of animals and plants are cross-referenced to their appropriate taxonomic groups.

1976 about £5.95 392pp

A Dictionary of Earth Sciences

Stella E. Stiegeler

The subjects covered here include geophysics, structural geology, geomorphology, oceanography, stratigraphy, palaeontology, sedimentology, climatology, meteorology, soil science, cartography, mineralogy, petrology and surveying. The terms defined reflect the recent modification of traditional concepts and the resulting development of terminology in the earth sciences. In soil science, for example, a new system of classification is now in use, with a completely new terminology for the soil orders.

1976 about £5.95 320pp

A Dictionary of Physical Sciences

John Daintith

This book covers the main branches of physics, chemistry and astronomy – from Abbe condenser to zoom lens and zwitterion. A selection of relevant terms from the related fields of electronics, computer science and mathematics is included. Full accounts are given of the properties and uses of the chemical elements and many of their compounds. All the chemical terminology used is that recommended by the International Union of Pure and Applied Chemistry.

1976 about £5.95 352pp

Complexes & First Row Transition Elements

D. NICHOLLS

An introductory text for students making their first detailed study of transition element chemistry. It concentrates on the first member of each group, since their properties differ significantly from those of subsequent members. The first part of the book deals with the chemistry of complexes—a topic of central importance to the study of transition elements. Throughout the text emphasis is placed on the properties and reactions of metal aquo-ions and the donor-acceptor properties of transition metal compounds.

£3.95 paperback

The Heavy Transition Elements

S. A. COTTON AND F. A. HART

A detailed account of all the transition elements except the first row (3d series). The book features a discussion of lanthanides and actinides, with emphasis on recent advances in their structural chemistry.

hardcover £8.95 paperback £4.95

reviews

Algal genetics

Lynn Margulis

The Genetics of Algae. Edited by Ralph A. Lewin. Pp. viii+360. (Blackwell Scientific: Oxford and London, 1976.) £11.50.

THIS book is a beautifully edited and profound review of the state of genetics of algae, which, as Lewin says, "are more of a guild than a clan, united more by common aptitude than by common ancestry". Although all algae have been taken to be within the province of the work, in fact there is very little serious genetics on organisms other than the green algal genus *Chlamydomonas*.

There are thirteen separately authored sections in the book. These include reviews of the recently established field of the genetics of blue green algae, the formal (mainly nuclear, mendelian) genetics of *Chlamydomonas reinhardtii*, genetic determinants of flagella phenotype in *C. reinhardtii* (a frustrating subject to study since flagellar alterations in these organisms which mate 'flagella first', tend to impair the frequency of viable crosses) and a short chapter on the genetics of cell wall formation in *C. reinhardtii*. The cell wall summary not only indicates how useful mutational analysis ultimately may be in the deciphering of the complexities, chemical and ultrastructural of cell wall morphogenesis, but indicates that there may be still another enigmatic "non-mendelian genetic system" in this chlorophyte.

C. reinhardtii, of course, is the star actor in any eukaryotic cell genetics drama and this is aptly indicated in the two chapters by Gillham, Boynton and their colleagues on plastid inheritance and genetic control of ribosomal biogenesis. The relationship of the three genetic systems (nuclear, plastid and mitochondrial) has nowhere been better investigated than in this rapidly growing isogamous organism, which may be mated at will, completes its life cycle in about a week and for which gene dosage and genotype-phenotype relationships can be studied since stable diploids can be made.

Information concerning the genetic systems of *C. moewusii* and *C. eugametos*—two other species of *Chlamydomonas* rivalling *C. reinhardtii* for centre stage—is reviewed. Since

stable heterokaryons can be made in *C. moewusii*, complementation can be studied in this organism. The reason why 2 amino-3 butanoic acid induces both gene mutation and chromosomal aberration in *C. eugametos* is still obscure. No such effect has been seen in *C. reinhardtii*. Other differences between the three species have been noted as well, providing internal tests for the possible generalisation of observations made on *C. reinhardtii*.

Although an exciting comprehensive, and up-to-date treatise, this book makes us acutely aware of how limited our genetic knowledge is concerning the algae as a group. There literally is no genetic literature as such on the red algae, the brown algae, the diatoms, the dinoflagellates, the chrysophytes, the prasinophytes, the euglenids, the haptophytes, and so forth. Although there is some scattered information concerning the mating and differentiating systems in *Volvox*, conjugating green algae, 'multicellular marine algae' and *Acetabularia* in chapters on the genetics of the Volvocales, Zygnematales, and Charophyta, respectively, even these sexual green algae have managed to hold on to their genetic secrets.

The classical techniques of controlling the life-cycle of marked genetic stocks, crossing individuals of opposite mating types and measuring the distribution of traits in offspring of these crosses are simply not available in the vast majority of algae for several different reasons. For example, the genetics of an organism such as *Euglena gracilis*, a flagellate which has yielded significant information concerning mitochondria and chloroplast inheritance and development, is impossible to study. Although chloroplast development and differentiation can be induced, these fast growing single cells simply refuse to mate. Thus, all of these chapters referred to above are forced to deal with "genetically related" phenomena (for example, hybrids produced by grafting in *Acetabularia*, nucleic acids of organelles).

Furthermore, the book is overwhelmingly concerned with the eukaryotic green algae: the Chlorophyta. As for the Cyanophyta or blue greens, they are a world apart. True to their popular new name (Cyanobacteria) they are

only rudimentarily sexual, anything at all about genetics is known in very few species. In general, they rely on proven prokaryotic mechanisms for gene transfer—transformation and transduction—in so far as any occurs. One new realisation is the nature of the circular genetic map as deduced from mutagenesis studies in synchronous cultures of *Anacystis nidulans*, a coccoid blue green: it really resembles in overall features, the genetic map of *Escherichia coli*.

Some idiosyncratic but profound algal genetic anecdotes come to light in this well illustrated and produced book. For example: in some blue greens recombination seems to be regularly accompanied by mutation; in *Ulva* the chromosomes are apparently composed of four rather than two DNA strands, and in *C. eugametos* a specific mutator gene reverses mutations at two nicotinamide loci.

Probably the most exciting advances concern the unravelling of biochemical interactions between the three classes of genetic organelles in *C. reinhardtii*: nucleus, mitochondria and plastids. Indeed sex in organelles exists and genetic maps have been made of a cytoplasmic genetic system. (Presumably these maps are of the chloroplast linkage groups: recombination of plastid DNA has been discovered.) There is even some evidence that a single mutation may alter both chloroplast and mitochondrial ribosomes simultaneously. Several chloroplast ribosomal proteins are apparently synthesised on cytoplasmic ribosomes even though the chloroplast DNA probably codes for all the chloroplast RNA.

The book is full of such well explained surprising genetic phenomena, and is highly recommended for advanced genetic and phycology courses and the professional reader. *The Genetics of Algae* is indispensable to those interested in genetic systems of the 'lower eukaryotes'. The book is well written, comprehensive and comprehensible. If more work on the other fascinating algal groups has not been reported here, it is because it has not yet been done. □

Lynn Margulis, Professor in the Department of Biology at Boston University, is on leave as Sherman Fairchild Distinguished Scholar at the California Institute of Technology, Pasadena.

Aggregation chimaeras

Mammalian Chimaeras. By A. McLaren. Pp. 154. (Cambridge University: Cambridge, London and New York, 1976.) £8.

It might be said that the laboratory mouse is the *Escherichia coli* of modern mammalian biology, since great things are expected of this species. Mouse genetics is one field in which the Woman's Liberation Movement is already passé, for the field has long been dominated by a group of outstanding ladies. Dr McLaren is certainly one of them. Her little book, as she lovingly calls it, certainly shows her intelligence and breadth of understanding.

Characteristically feminine attentions to details are most pleasing. The subjects are mostly what have variously been called allophenic or tetraparental mice produced by the fusion of two blastocysts, but Dr McLaren prefers to call them aggregation chimaeras. Injection chimaeras refer to those that are produced by the injection of one or more cells into a blastocyst of a different genotype as practiced by Richard Gardner. These animals are very useful for analysis of clonal differentiation of embryonic cells. Degrees of intermingling that inevitably occur between neighbouring clones can also be assessed. They are also ideally suited to distinguish genetic effects that are mediated through humoral factors from those that are

exclusively intracellular. The wealth of information accumulated by Tarowski, Minz, McLaren, and by a number of others, is presented in a very orderly manner and in sufficient detail.

Inevitably, a few very important pieces of information apparently failed to make the deadline, but who can blame the author for this. For example, M. F. Lyon's recent demonstration that totally androgen-insensitive *Tfm/Y* male germ cells in the body of chimaeric male mice can mature and differentiate to functional spermatozoa was nearly a fatal blow to those who believed in the androgen dependence of male germ cells. Similarly, the discussion on the great preponderance of males among XY/XX chimaeric mice would have become more meaningful if more recent findings on H-Y antigen's testis-organising functions were introduced.

With regard to immunology, another recent finding that Ia antigens, controlled by at least two immune response (Ir) loci, are very strongly expressed on B cells, but only very weakly on most T cells, would surely have modified Dr McLaren's discussion of findings on chimaeric mice between high responder and low responder strains.

I believe that almost every problem-solving biologist who deals with higher vertebrates would find this book instructive and informative.

Susumu Ohno

Susumu Ohno is Chairman of the Division of Biology, City of Hope National Medical Center, Duarte, California.

Practical problems of the visual world

Vision and Acquisition: Fundamentals of Human Visual Performance, Environmental Influences and Applications in Instrumental Optics. By Ian Overington. Pp. xix 380. (Pentech: London; Crane, Russak: New York, 1976.) £14.

THIS is an unusual and useful book. Its main value is that it focuses attention on the problem of how a human detects and recognises a target in adverse conditions.

Although much of the work described was undertaken for military purposes, many of the results are pertinent to civilian life—for example, the flying of modern high speed aircraft poses many human problems particularly in visual performance. But even at the lower speed of driving a car many accidents are believed to occur because of a failure in visual perception or recognition. This is

particularly true in motorway driving in poor visibility, often resulting in a tragic loss of life and injury.

The book is particularly valuable in that it contains many references to special reports that most visual scientists would not come across. There are a few errors particularly when the physiology of vision is discussed, but none of these are of a misleading nature.

I hope that this book will encourage some laboratory bound visionaries to look out of the window and consider the practical problems that the visual world presents. Conversely, it may also encourage engineers to pay more attention to modern visual physiology and possibly even to seek the advice of visual scientists more frequently.

The book is very neatly presented and illustrated, and bears the high price of today's publication costs.

F. W. Campbell is Reader in the Department of Physiology at the University of Cambridge, UK.

Virology symposia

Animal Virology. (ICN-UCLA Symposia on Molecular and Cellular Biology. Vol. IV. Edited by D. Baltimore, A. S. Huang and C. F. Fox. Pp. xi+824. Academic: New York and London, 1976.) \$29.50; £18.

THE ICN-UCLA Symposia on Molecular and Cellular Biology held each spring at skiing resorts in California or Colorado provide a pleasant and useful forum for the subjects discussed. Baltimore, Huang and Fox organised what seems to have been a most interesting meeting on animal viruses, that even included a session on plant viruses. Much of the emphasis was on viruses known to be oncogenic, including an interesting session on cell transformation and differentiation, but there were also sessions on the molecular organisation of negative-strand RNA viruses, on viral messenger RNA synthesis, and on viral protein synthesis. Thus, as the organisers say in the preface (as editors of the published proceedings), "this meeting considered broad issues and recent advances in animal virology, and treated tumor viruses in the context of the range of animal viruses rather than as a separate problem."

In my opinion this volume should never have been published. True, it is one of the better volumes of its kind, but I deplore the practice of routine publication of symposia proceedings. It clutters up the literature and overburdens library budgets. Perhaps some of these volumes are profitable to publishing companies: they are not profitable to scientific endeavour. The only purpose it serves is to amplify the contributors' publication lists. The ICN-UCLA symposia are published by typescript photo-reproduction methods and appear about 6 months after the meetings are held. Most of the papers in the volume under review had by that time been printed with essentially identical data in academic journals as proper publications. Those that have not, may have been disapproved by reviewers and editors. The symposia proceedings are not subject to review and there is no distinction between invited and proffered papers.

Scientific organisers of symposia are usually apologetic on requesting manuscripts for publication, explaining that the financial sponsors demand them. The sponsors should realise that the meeting is important, not the publication, and there are other ways of making the sponsorship known. It is time that scientists declined to present talks on current research at symposia if publication is obligatory.

Robin Weiss

Robin Weiss is a member of staff at the Imperial Cancer Research Fund Laboratories, London, UK.

Bioengineering

Applied Biochemistry and Bioengineering. Vol. 1: Immobilized Enzyme Principles. Edited by L. B. Wingard, Jr, E. Katchalski-Katzir and L. Goldstein. Pp. xi+364. (Academic: New York and London, 1976.) \$29.50; £20.95.

RECENTLY there has been a spate of books on bioengineering in general and enzyme technology in particular. Many are collections of unrelated articles of very variable quality. Therefore it is pleasant to note that this first volume of a new series has a coherent theme which is well treated. The editors do have a particular reason to organise the volume well. Wingard has done much to stimulate interest in enzyme technology, and Katchalski-Katzir and Goldstein were pioneers in the fundamental studies of immobilised enzymes. Appropriately the latter two editors begin the book with a concise survey of developments in the field which serves to introduce subsequent contributors. Goldstein is also co-author (with Manecke) for the second chapter on the chemistry of enzyme immobilisation. The systematic treatment of the available methods with comment on their advantages and disadvantages will be welcomed by anyone who has to make a selection from the bewildering number now available.

Engasser and Horvath deal with diffusion and kinetics of immobilised enzymes.

Synaptic connections

Neuronal Recognition. By S. H. Barondes. Pp. xvi+367. (Plenum: New York and London, 1976.) \$33.

THIS collection of eleven essays is concerned with the problem of how neurones establish synaptic connections with certain targets and not with others. As a result of studies on the developing and regenerating nervous system, we now have a reasonable picture of the degree of discrimination in several situations, but not of the underlying cellular and molecular mechanisms. The essays vary from relatively general reviews to quite detailed accounts of work from the authors' laboratories. Together, they provide a good overall view of approaches to the problem.

The existence of specificity, as well as its extent and possible basis, is considered for the retinotectal system (Jacobson), for the neuromuscular junction (Fambrough), for sprouting in the central nervous system (Cotman and Lynch), and for synaptogenesis in tissue culture (Bunge). Morphological information about early events in synapse formation is considered by Pfenninger and Rees, and the current unsatisfactory state of biochemical methods for purifying and

They draw heavily on the results of their collaborative studies in dealing, for example, with the effect of external diffusion limitation on the observed behaviour of enzymes immobilised in porous particles or membranes.

The review of the design and analysis of immobilised enzyme flow reactors by Vieth *et al.* is well documented but the reviewer would arrive at some different conclusions. The authors state that 'batch reactors have limited potential in industrial immobilised-enzyme catalysis.' Most of the semisynthetic penicillins produced industrially in Europe and a growing proportion elsewhere are made by means of batch conversion using immobilised enzyme.

The industrial application of immobilised enzymes and immobilised microbial cells are described with technical and economic details by Chibata and Tosa, whose Japanese company was the first to announce the use of both types of catalyst in modern industrial processes. It is interesting that glucose isomerisation, which originated in Japan but was developed as the largest-scale current use of immobilised cells or enzymes in the USA, is not dealt with in any detail, presumably because it does not have the same economic importance in Japan. **P. Dunnill**

P. Dunnill is Lecturer in Biochemical Engineering and co-leader of the enzyme and protein technology group in the Department of Chemical and Biochemical Engineering at University College, London, UK.

fractionating neural plasma membranes is critically reviewed by Morgan and Gombos.

The second half of the book is concerned with attempts to assay and identify molecules involved in cell recognition in various situations. Although there is, as yet, no direct evidence on the relevance of these studies to synapse formation, they are clearly of great interest to students of specificity. Three of these essays are concerned with investigations of cellular aggregation and adhesion in the retinal and retinotectal systems (Moscona; Roth and Marchase; Merrell, Gottlieb and Glaser). The morphogenetic role of extracellular glycosaminoglycans is considered by Toole, and Barondes and Rosen discuss cell surface lectins and cell recognition in slime moulds.

Most of the essays are thoughtful, well organised and often helpfully illustrated. Neurobiology sometimes seems impenetrable to outsiders, but I would strongly recommend this volume to interested investigators in other areas of cellular and molecular biology, as well as to graduate students and specialists in the field. **Jeremy Brockes**

Jeremy Brockes is a member of the MRC Neuroimmunology Project at the Department of Zoology, University College, London, UK.

Fourier transform NMR spectroscopy

Fourier Transform NMR Spectroscopy. By D. Shaw. Pp. xvi+357. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl. 129; \$49.75.

FOR a great deal of chemical structural and diagnostic work using proton nuclear magnetic resonance (NMR), a simple continuous wave (CW) spectrometer is entirely adequate, but in cases involving very small molar quantities of sample or for measurements on other nuclei, Fourier transform (FT) spectrometers are needed. The CW spectrometer scans slowly across the spectrum, using a continuous monochromatic radio frequency to stimulate each resonance in turn. In the FT spectrometer, a brief but strong pulse of radio frequency is applied to the sample so as to stimulate all the resonances simultaneously. The response of the nuclear spins after the pulse is collected, and because the components of all the resonances are mixed up together (and in the time domain) a computer is needed to disentangle them and produce the more familiar spectrum (in the frequency domain). Because all the resonances are stimulated simultaneously, there is a substantial gain of signal-to-noise for complex spectra, and because the method uses pulsed radio frequencies, relaxation times are more easily measured than with the CW method.

Dr Shaw has produced an excellent handbook for those spectroscopists who are extending their activities from the CW to FT methods. In chapter 3 the mathematical principles are outlined, not in an attempt to provide rigorous accounts of the theorems, but to ensure that the physical principles are clear and the equations used can be understood. Chapters 4 and 5 give a clear description of the various ways of exciting NMR spectra and their relative advantages; and chapters 6 and 7 explain in some detail the experimental methods available, the equipment required, how it works, and the ways in which it may be used. These chapters form the core of the book and will be of great value to all those who need to use FT spectrometers.

Chapters 1 and 2 give a brief introduction to the principles of NMR spectroscopy; and chapters 8, 9, 10 summarise many of the ways in which NMR spectroscopy can be applied to chemical problems and how the measurable parameters can be obtained. These chapters cover a lot of ground and are useful mainly as a convenient outline and reminder to readers already acquainted with the subject. **R. E. Richards**

R. E. Richards is Warden of Merton College, Oxford, UK.

Machiavellian weed

Wild Oats in World Agriculture: An Interpretative Review of World Literature. Edited by D. P. Jones. Pp. xi+296. (Agricultural Research Council: London, 1976.) £3.

It is unusual, if not unique, for a weed to achieve the distinction of having such a comprehensive publication devoted to itself, an accolade most often accorded to a crop species. The impetus for a review at this time has been dictated primarily by the requirements of agriculture for greater understanding of the biology and control of this pernicious species. It is perhaps Joan Thurston at Rothamsted, however, who must be acknowledged as having foreseen in the post-war period the emergence of this species as a primary constraint to the cereal producer and initiated much needed research and the collection of material from throughout the world, on which so much of the information on distribution of *Avena fatua* is based.

The significant contribution to the systematic appraisal of the biology and agronomy of wild oats by the Weed Research Organisation in the last decade is reflected in the authorship of this book. A leavening of the text, however, with some contribution from outside the UK, would have been useful in consolidating the purported world aspect of the review. Research in Canada with respect to the fundamental mechanisms of seed dormancy and at a more general agronomic level has been considerable. The whole nature of the problem in North America, with its extensive low input cereal production system, stands in stark contrast to the situation in Western Europe: the role of Government and statutory controls could also have been treated in a somewhat wider perspective.

A wealth of information has been gathered together in this volume. In this topic, there undoubtedly exists the basis of a classic contribution, not just to agriculture or botany but of relevance to many areas within the broad biological discipline. There are so many elements in the biology of the wild oat of wide and general significance—a weed par excellence and one whose resources and versatility, strengths and weaknesses, have been so well documented to exemplify the myriad facets of a successful weed—that it is to be hoped that this volume will achieve a circulation outside that of the specialist agriculturalist for whom it was mainly intended. The mechanisms of seed

dormancy and seed dissemination, the population dynamics in the context of agricultural practice, the niceties of selective herbicide usage which now allow a distinction to be drawn between the 'wild' and cultivated varieties of oats, are examples of situations of wide biological relevance.

My prime reservation is that the authors have aimed this work at a specialist readership, whereas the subject has a great deal of popular appeal and that the fascinations of this Machiavellian weed have been subjugated, if not totally submerged, by the bulk of references and verbiage.

On a more specific level, although the chapters follow a logical sequence there are incongruous aspects to the

section and subsection headings in certain chapters. A degree of unnecessary duplication of material between topics is also to be found although, with the exception of minor omissions in pagination, the difficult task of adequate cross referencing has been well accomplished.

In all, this volume stands as a novel concept within, and a valuable contribution to, the field of the biology and control of weeds, and at such a modest price represents exceptional value.

Alan D. Courtney

Alan Courtney is Lecturer in the Department of Agricultural Botany at the Queen's University, Belfast, Northern Ireland.

Laser applications

CO₂ Lasers: Effects and Applications. By W. W. Duley. Pp. xiii+427. (Academic: New York, San Francisco and London, 1976.) \$31; £18.40.

THE preface to this book is more informative than its title: the volume outlines a very wide range of laser applications in physics, chemistry and engineering, with the CO₂ laser receiving special rather than exclusive attention. In places the treatment is distinctly pragmatic. For example, in the forty or so pages dealing specifically with CO₂ laser devices, optimisation of optical cavity transmission is treated entirely experimentally, with no discussion of Rigrod's formulation. A second example is provided in the surprisingly brief treatment of unstable optical resonators, where there is no interpretation of the specific experiments cited.

Readers may feel that chapter 3 redeems itself with the very detailed information provided on infrared detectors, windows, modulators and mirrors, although diamond turning techniques receive no mention. The first half of the book concludes with selected solutions to the heat-conduction equation, a subject previously, exhaustively and authoritatively treated by Carslaw and Jaeger. Moving heat sources, liquid phases and vaporisation do, however, provide interesting variations to this theme, and are required for a proper understanding of surface heat treatment and welding; here, an important reference (Swift-Hook and Glick, 1973) has been inadvertently omitted in the references.

An interesting survey of drilling by argon, ruby, Nd-YAG and CO₂ lasers is followed, in chapter 6, by a somewhat dated discussion of welding and machining. In particular, Table 6.5

contains several errors and omits any specification of spatial mode quality of the laser, or of focal conditions—factors which may account for some of the relatively poor cutting speeds tabulated. The laser-induced reactions, evaporation and thermal effects touched on in chapters 7–9 are uniformly intriguing, and could interest a diverse selection of *Nature's* readership. These applications include: laser cleansing of surfaces, the deposition of thin films, chemical vapour deposition, surface studies and reactions, geological analyses, laser-triggered spark gaps, resistor-trimming, pyrolysis of coal and oil shale, gas-phase reactions and spectroscopy, crystal growth, metallurgical effects, and controlled stress generation in solids and liquids. This coverage is clearly too wide to permit detailed evaluation of specific topics; in particular, isotope separation and (thermal) surface heat treatment are both treated too briefly to be of interest to specialists in these fields. The book concludes with a chapter discussing propagation, atmospheric monitoring and the communications possibilities of the CO₂ laser. Pollution monitoring to parts in 10⁻⁹–10⁻⁸ using tunable diodes, spin-flip CO, CO and CO₂ lasers, and the back-scattering efficiency for typical particulate atmospheric constituents, are discussed in some detail. A systematic comparison of LIDAR performance using a range of laser sources is however, not attempted. Three appendices provide a useful compendium of thermal constants for a range of engineering materials.

The book is well produced, reasonably priced, and provides an interesting introduction and bibliography to the scientific and technical literature.

I. J. Spalding

I. J. Spalding works on laser applications at the UKAEA Culham Laboratory, Abingdon, UK.

Extraversion-introversion paradigm

The Measurement of Personality. By H. J. Eysenck. Pp. xviii+511. (MTP: Lancaster, 1976.) £12.50.

EYSENCK is remarkable in many ways, not least in his ability to generate books both as author and editor. This one, a collection of reprints, linked tightly and at length by editorial argument, deals almost entirely with the personality dimension of extraversion/introversion but has no overlap with the papers covered by his recent three-volume work on the same topic.

Nevertheless, the papers are carefully selected to exemplify and support the case for Eysenck's particular approach to the study of personality which he describes as a 'paradigm' in the Kuhnian sense of a professional or disciplinary matrix. This paradigm is closely modelled on physical science, depends on measurement and hypothetico-deductive procedures but goes beyond Popper to Lakatos' view of a research program which yields predictions of novel facts but tolerates anomalies among its findings; and in fact progresses from experimental analyses of these anomalies.

Eysenck's program is based on the claims that there is a set of invariant general traits underlying individual differences in behaviour, that these are explicable in terms derived from general experimental psychology, and that the broader and more important personality factors are likely to derive from more basic biological variables which, in turn, are largely determined by genetic factors. Apart from intellectual abilities he believes that there are only three higher order factors of this type. Extraversion/introversion (E) is one of these and the related behaviour is postulated to be a non-linear function of individual differences in characteristic levels of "cortical arousal". Sections of the book deal with models of personality, its physiological basis, differential reactions to pain and other sensations, and individual differences on vigilance tasks, in perceptual reactions, motor behaviour, learning, memory, fluency and creativity, and in social behaviour.

Many of Eysenck's opponents consider his objective, nomothetic approach inappropriate for the study of personality and engage in a holistic idiographic search for understanding, which he sees as fruitless. Others remain within his frame of reference but lay greater stress on the situational determinants of behaviour, which he

regards as largely irrelevant or as interfering factors to be controlled in his studies. He does recognise that they may have an important function in certain real life situations but even then stresses their interactions with an individual's personality. Other critics also quarrel with the heavy weighting Eysenck grants to heredity in his rather "either/or" approach to nature/nurture questions. A particular phenotype is the outcome of a developmental process in which experience may affect organismic maturation in a number of ways: by channelling it in certain directions but also by facilitating or inhibiting normal development. This is particularly true of early neural maturation, which plays an important role in Eysenck's theory.

The great strengths of Eysenck's personality program, however, are that it embraces more levels of functioning—biological, behavioural and social—in a more comprehensive way than any other and that it is closely related in an interactive developing fashion with an ongoing experimental research programme. In this book he certainly substantiates his claim to a "paradigm" and a theory in transition from "soft" to "hard". His critics should read this book with care: they will not find it easy to produce an equally powerful counter-argument.

H. Gwynne Jones

H. Gwynne Jones is Professor of Psychology at the University of Leeds, UK.

Solar flares

Solar Flares. By Z. Svestka. Pp. xiv+399. (D. Reidel: Dordrecht, The Netherlands and Boston, Massachusetts, 1976.) Cloth Dfl115; \$39.50; paper Dfl69; \$23.

THERE may be a temptation to regard Svestka's book as an update of Smith and Smith's work of the same title published fourteen years ago. To do so would, however, be to grossly underestimate the magnitude and success of Svestka's undertaking in this new book. For, firstly, the quantity of observational material to be reviewed has expanded since 1963 with a growth rate perhaps exceeded only by solar flares themselves. And, secondly, although the subject matter is intended primarily to be observational, an admirable awareness has been retained throughout of the need for objective interpretation in the areas of both classification and physical theory.

Approximately one-third of Svestka's efforts are devoted to the chromospheric flare as observed in optical wavelengths, and to flare-associated optical phenomena. Although this distribution may still reflect some of the historical overemphasis of hydrogen Balmer line observations, it seems well justified in view of Svestka's personal expertise in this area, and, also of the observations being well tempered by theoretical discussion of such matters as inference of magnetic fields and models of chromospheric flare heating.

A comparable section is dedicated to "The High Temperature Flare" embracing not only the thermal XUV emissions but also the non-thermal hard X-ray and radio bursts. Much of this material appears here in mono-

graph form for the first time, having been born of the advances in space techniques over the past decade. The coverage given to Skylab and other recent results is remarkably good for a review of such a rapidly expanding field. Ample attention is again given to basic data interpretation and to detailed physical models where these exist—specifically for hard X-ray, microwave and Type III sources.

Following a chapter on particle emission, Svestka finally turns to the matter of flare models. In a sense, this is the weakest section since many different models are rather cursorily dealt with. This is not surprising since a second volume by the late L. D. de Feiter had been planned on purely theoretical aspects. Given, however, the current motley state of flare theory, and the complexity of the plasma physics involved, it is perhaps better simply to relate the broad features of models to observational manifestations rather than to attempt a survey of this difficult and incomplete area of theory.

Finally, it might have been appropriate to set the flare problem in a wider plasma astrophysical context such as theory of flare stars and energetic galactic phenomena. To do so would, however, have been to enter speculative realms not in keeping with the systematic objectivity which characterises this book and Svestka's work in general. This quality alone should suffice to remind astrophysicists of the intrinsic interest of the flare phenomenon, and certainly makes the book a must for all solar physicists.

Biological effects of environmental agents

Biochemical Toxicology of Environmental Agents. By A. de Bruin. Pp. x + 1544. (Elsevier/North Holland: Amsterdam and New York, 1976.) Dfl. 320; \$130.75.

INTEREST in the biological effects of environmental agents has increased enormously in the past three decades, stimulated by the growing awareness of the potential threat to human health of the increasing number of chemicals in the environment. There has been a corresponding increase in the number of toxicological investigations (in man and experimental animals) and these have come to rely more and more on biochemical techniques both in the assessment of toxic effects and in the study of the mechanisms of toxicity.

Dr de Bruin's book provides in 42 chapters an up-to-date review of the many aspects of biochemical toxicology. The first chapters are fairly general in scope, dealing with the metabolism of foreign chemicals, with factors which modify metabolism and toxicity, and also with tests of exposure to toxic compounds. There follows a systematic treatment of the various aspects of toxicity which are considered in different chapters,

according to the biochemical or biological system which is affected. Thus, disorders of carbohydrate and lipid metabolism are first considered, then proteins, nucleic acids and so on, and, finally, immunological mechanisms and blood coagulation disorders. Each chapter has a short introduction outlining the normal biochemical principles relevant to the system, followed by the biochemical toxicology of chemical agents and the effect of ionising radiations.

Dr de Bruin's book will be a useful reference work. The amount of information presented is vast (about 13,000 references are quoted), and the book is unique in providing so much information on so many different aspects of biochemical toxicology in one single volume. That a single author should have been capable of covering so much ground on his own is in itself, a very considerable achievement.

Perhaps inevitably for a book of this size, treatment of the biochemical mechanisms of toxicity is sometimes superficial; the author presents all the data available in an exhaustive fashion with little critical appraisal, so that the reader is left without guidance as to which of the various findings reported are of particular significance.

Secrets of the Universe still locked up

The Universe. By J. Kleczek. Pp. vi + 259. (Reidel: Dordrecht and Boston, Massachusetts, 1976.) Cloth Dfl. 70; paper Dfl. 43.

THE idea of a book about the Universe linking the large and the small (galaxies and elementary particles), and starting from particle physics and the four basic forces to build outward, is a good one. Unfortunately, this is not a good book. The principle reason for this is the severe tailoring required to fit a quart story into a one-pint volume; as the preface says, this is only achieved by giving no references, short-cutting arguments, expressing quantities often as orders of magnitude and keeping formulae to a minimum. As well as all that, the author's English is not always very readable, and the text could have been improved by some sympathetic editing.

Of all these shortcomings, the worst is that where several theories or hypotheses exist to explain some pheno-

menon—as is so often the case in studies of the Universe—the author chooses only one for discussion, and presents it uncritically. On the solar neutrino problem, the author's treatment is even more deficient; we are simply told that "Many suggestions have been made to explain the discrepancy. There is no lack of ideas", without being told what any of the ideas are. The confused reader will gain little comfort from the index, in which some topics are broken down in nit-picking detail, whereas others receive no mention; the entry under "B", for example, consists solely of "Big-Bang", with no mention even of black holes, although they are discussed in the text.

If the same material, arranged under the same chapter and section headings, had been expanded to twice the size of the present book and edited into smoother English, the result would have been a valuable addition to the astrophysical literature. As it is, the present volume adds nothing of any value and cannot be recommended.

Ecophysiology

Introduction to Physiological Plant Ecology. By P. Bannister. Pp. 273. (Blackwell Scientific: Oxford and London, 1976.) £4.75.

PLANT physiological studies have contributed, and continue to contribute a great deal to plant ecology, and many universities and colleges now teach undergraduate courses in ecophysiology. Many such courses have arisen from a desire to present plant physiology in its true evolutionary and environmental context. It is natural, therefore, that publishers have been anxious to provide suitable texts for such courses and the book reviewed here follows others by Etherington (*Environment and Plant Ecology*, Wiley, 1974) and Larcher (*Physiological Plant Ecology*, Springer, 1975).

Bannister covers the expected ground—energy balance, responses to light and temperature, soils, mineral and water relations and competitive interactions. The approach is concise and basic. He starts from first principles and relies mainly on verbal rather than numerical explanation of the principles discussed. This makes the text readable; also, it is rich in pertinent illustrations, largely drawn from British examples.

The attempt to portray such a wide and complex subject at an elementary level has necessitated a considerable degree of selection and pruning, and some topics are dealt with very briefly and may, consequently, be oversimplified. As a general criticism, I feel that too little information has been provided on relevant metabolic processes, which leaves one rather dissatisfied with some explanations. For example, an interesting collation of data concerning the tolerance of extreme temperatures by plant species stops short of explaining their metabolic consequences or the biochemical adaptations involved. At times the avoidance of biochemistry even obscures the text, as in the case of the C-4 photosynthetic system and the explanation of photorespiration. The same, however, applies to Etherington's book on this point.

Bannister's book stands out from the crowd by virtue of its rich use of examples of field problems which have been illuminated by physiological work. One can point students to it with the confidence that it will simulate their interest.

newly on the market

These descriptions are prepared by the staff of *Nature* on the basis of material provided by manufacturers. There is a Reader Enquiry Form facing page 28.

25 MHz oscilloscope. Pye Unicam. A 25 MHz oscilloscope with full digital measuring facilities found normally only on higher frequency models, the Philips PM 3214 has all the features of a general purposes oscilloscope with high 2 mV sensitivity over the full bandwidth. Digital measurements are facilitated by such features as a delayed timebase with fully calibrated delay and an alternate timebase facility which allows display of both main and delayed timebase signals at the same time for direct and easy reference. The wide range of power supply possibilities allows the oscilloscope to operate in the laboratory or the field. Mains supplies of 110, 127, 220 and 240 V a.c. $\pm 10\%$ at 46–440 Hz, 21–27 V d.c. supplies or an internal 24 V battery option are the alternatives. Power consumption of the oscilloscope is 30 W.

Fluorescence detector. Perkin-Elmer Ltd. A new fluorescence detector for liquid chromatography, LC-1000, has been designed with emphasis on high sensitivity, selectivity and ease of operation. The LC-1000 uses a xenon source providing a continuum over the UV/visible region. The square section quartz flow cell of 20 μ l volume is designed to provide maximum sensitivity, minimum scatter and no detectable loss of peak resolution while still being simple to dismantle for cleaning. Model LC-1000 uses a continuous interference filter as an emission monochromator operating over the region 390–750 nm, and the ability to scan an emission spectrum of a peak in a chromatogram can provide peak identification—a unique advantage. For wavelengths below 390 nm the fluorescence can be monitored by any fixed interference filter.

Photomultiplier power supply. EMI. The Type PM28A has the following characteristics from the electrical specification: output voltages from 100 to 2,800 V, ripple better than 2 mV peak-to-peak, temperature coefficient less than 50 p.p.m. per $^{\circ}$ C and load regulation 10 p.p.m. from a no load to full load (5 mA) change. An additional

feature is that the unit can be reset to within 0.2 V throughout the voltage range so that photomultiplier tube gains can be reproduced accurately. The unit is capable of positive or negative output, with options for remote programming and kits are available to mount units either singly or two abreast into a 19-inch rack.

Multiple sample harvesters. Ilacon Ltd. Designed for use in lymphocyte transformation assays, and a wide range of other isotope assays carried out in microplates, these harvesters introduce two unique design features which ensure trouble free and efficient operation. The basic model uses a patent disk cutter system to cut and hold the glass fibre filter paper, and a wash trough which allows complete versatility in washing without the need for switches or valves. Alternative models allow either supernatant collection or a disk clamping system for harvesting on to intact sheets of filter paper.

Will Z-33 zoom stereomicroscope.

Will Z-33 zoom stereomicroscope. Will-Strübin. The Will-Strübin stereo zoom microscope has a magnification range from $\times 2.7$ to $\times 180$. The eyepieces give extra wide field vision, and the eyepiece sleeves are adjustable and inclined 45° which guarantees comfortable vision in the normal sitting position. Various accessories are available including transmitted light universal stands, camera attachments, eyepieces $\times 5$, $\times 10$, $\times 15$, and $\times 20$, also auxiliary lenses and fibre optics.

Circle No. 46 on Reader Enquiry Form

Multipoint thermal printing recorder. International Instruments Ltd. The Speed Servo II combines a linear servo motor with a simple solid state semiconductor printing device that ensures positive multipoint channel identification. The printhead thermally brands the three basic types of readout: the channel number and a dot, all dots, or mixed dots and numbers as programmed. Models with up to 24 independent channels are available and the print rate can be as fast as one second per point full scale. The channel identification numbering system automatically prevents confusion when input values cause the traces to overlap, especially when all channels are in use, saving time in chart reading and analysis.

Circle No. 47 on Reader Enquiry Form

Liquid chromatographs. Perkin-Elmer. Series 2/1 is a single module providing both solvent delivery and sample injection and features high pressure capability, rapid solvent changeover, unlimited solvent supply, precise and steady flow, and a wide flow range adjustable from 0.1 ml min $^{-1}$ to 29 ml min $^{-1}$ for analytical and preparative separations. Series 2/2 combines the operating features of two Series 2/1 pumps and a sample injection system. The instrument provides linear solvent and flow programming capability from 0.1 ml min $^{-1}$ to 30 ml min $^{-1}$. Series 2/2 also offers direct mixing of selected solvent compositions, preparative flow rates, and allows independent solvent changeover.

Circle No. 48 on Reader Enquiry Form

Bench-top chemostat. New Brunswick Scientific Co., Inc. This accurately defines growth parameters such as agitation, aeration, temperature, nutrient addition and harvesting of cells grown in pure culture. The BioFlo can also be equipped with miniature probes and controllers for dissolved oxygen and pH regulation. With a working volume of only 350 ml, it is possible to sustain cell growth for a minimum of 38 h without replenishing the medium. The BioFlo can be operated at temperatures from below ambient to 60 $^{\circ}$ C. A magnetically coupled agitator produces a homogeneous dispersion of culture medium under aseptic conditions at speeds from 200 to 1,000 r.p.m.

12 May 1977

A modest proposal to the Department of Education and Science

THERE is by no means enough lobbying of government on behalf of science. That was the challenge thrown out last week by Mrs Shirley Williams, Britain's Secretary of State for Education and Science, at a gathering of the Association of British Science Writers. The Arts, for which she is also responsible, lobby regularly and aggressively; science's voice is rarely heard. This will come as a surprise to many scientists who have assumed that lobbying would be unwelcome and counter-productive. But the challenge is not just to scientists; it is to Mrs Williams herself to find ways of opening up the London machinery to the community at large so that access to decision-makers becomes easier to achieve.

That British scientists don't do enough to express their opinions is undeniable. Certainly when an issue like the payment of CERN's subscription comes up there is a great flurry of activity, but for the most part the British scientist is totally silent—content, presumably, with zero growth rates and a secure job. Maybe the assumption is that the media will look after all questions concerned with policy and will spot all issues which ought to be raised; and then, when there is nothing in *Nature*, *New Scientist* or the *Times Higher Education Supplement*, it is assumed that there is really nothing to worry about. This would be a dangerous assumption; the media cannot hunt out what it knows nothing about, and certainly in the past few years the number of individual scientists who have approached us with a request that we should look into something or pursue a particular campaign is pathetically small.

Or maybe it is widely believed that worthy bodies like the Advisory Board for the Research Councils or the individual research councils themselves adequately look after the interests of science. The trouble with that assumption is that these bodies already have a fairly clear and well-charted relationship with the Department of Education and Science, and this allows relatively limited scope for anything resembling lobbying, which would, in any case, have to be done by chairmen themselves. What,

presumably, Mrs Williams is looking for is a regular flow of opinion of diverse sorts, not just from research council heads, on how support for science should develop.

It would be too easy, however, to lay the blame for the lack of lobbying entirely on apathy in the country. That apathy has very largely been fostered by the way in which British society divides its institutions so scrupulously. There is Parliament. There is the civil service. There is the law. There is industry and commerce. There is the military. There is the academic world. And there is the press. All too rarely do people find it easy to cross these frontiers and live happily in two or more camps either concurrently or consecutively, and as a result public life suffers through narrowed horizons.

Obviously there is no simple remedy to this. Over-secure career prospects and innate beliefs that certain ways of earning a living are superior to others are not going to be done away with overnight. But there is some positive action Mrs Williams could take to get to hear the scientist's voice; she could create a post for a distinguished scientist who with a small staff could act as the department's ears and eyes into the scientific community—and not just academics. Maybe such a person would be called Chief Scientist, but his or her function would be rather different from those of chief scientists in other ministries. In many ways the job of being a link with practising scientists used to be performed by the government's chief scientific adviser, but now that this position has been allowed to lapse there is no one to whom scientists can turn in a personal capacity. The department's chief scientist ought to fulfil that role, but in doing so ought to be highly mobile. The attractions of life in London close to the corridors of power are obvious, but the right person would not be bound to an office but would be regularly on the road, thereby not just hearing what institutions and professional bodies have to say, but more importantly seeking out the opinions of individuals. □

Today's risks: thinking the unthinkable

Reg Farmer, Safety Adviser to the UK Atomic Energy Authority and Visiting Professor at Imperial College of Science and Technology, offers his perspective on risk in modern society

THERE is growing concern over the safety of our industrial and social activities. People ask, "Is it safe?" For many years we have been told about the risks from radiation; now we hear of the potential hazards to people or the environment from mercury, lead, asbestos, aerosols, and recently from saccharin.

There have been various attempts to draw a dividing line between 'safe' and 'unsafe' or even to establish absolute safety—a state of no risk. In the early days of atomic energy in the UK, there was an attempt to find a design of reactors which was inherently safe—any move to danger would be self-cancelling. More recently some people claim that if any risk can be identified, it must be eliminated. Neither of these approaches has proved to be achievable in practice.

In the USA it was first implied that reactors would be safe if contained, and there was a proposal to design a 'zero release' containment, so as to appear to give absolute safety. Later there grew a recognition of some risk—in the USA a three-man hearing was required to satisfy itself that the proposed nuclear plant created no undue risk. 'Undue' did not mean no risk, but it introduced the concept of reasonable. No specific directive was given as to that which might be judged reasonable other than through the circular statement:

To understand 'undue risk' in this context it is necessary to understand 'reasonable assurance' and AEC has defined this as meaning 'reasonable probability, establishing under the particular circumstances of the case in good faith and in the exercise of sound discretion and expert judgment.'

A not dissimilar situation arises in relation to the use of some chemicals, fertilisers, insecticides, food additives and so on. Generally their use should be controlled by the best possible means. In some cases and in some countries absolute criteria apply—as in the US Food and Drug Administration requirement that any foodstuff shown to produce cancer shall be banned. It is not then a question of what is reasonable, but a pursuit of no risk. This absolute criterion is not in keeping with the acceptance of risk at work, at play, or risk through the continued low level contamination of our environment.

It would be convenient if the answer to the question, "Is it safe?" could be yes or no. For thirty years, throughout the development of atomic energy, there have been many and varied attempts to derive criteria which, if satisfied, would imply safety or adequate safety and, if not satisfied, would imply some risk. For some years it was claimed that pressure vessels could not fail catastrophically if they were maintained at some appropriate temperature (nil-ductility temperature + 60 °F). There have been many attempts to find an all-embracing solution, by proposing an upper limit accident which the system should be designed to tolerate safely, to circumscribe all lesser accidents—such as the assumption that the largest pipe could fail or that, in gas-cooled reactors, the coolant flow might cease instantaneously.

These early accident studies followed a pattern, now called deterministic; this emerged when it was recognised that, in general, no system is inherently safe. It was at one time suggested that we should take account of two co-incidental faults, but not three. This approach has been

revised in various ways, such as a requirement that there should be two or three 'boundaries' between fission products and man. These requirements are largely illusory and do not define what risk level is being accepted.

I would like now to consider some other aspects of the current risk scene. It would appear that some hazards are thought to be more unacceptable than others, such as the results of thalidomide, the effect of dioxin or of radiation. It is easy to understand the horror of continued evidence of mistake or misfortune, as presented by malformed children. It is not easy to identify or justify the fear of exposure to radiation as against exposure to toxic chemicals.

Radiation and radioactive substances have been with us always; some say the new situation arises because of the bomb; others that it arises from the fear of cancer, as may be evidenced by the USA ruling on the prohibition of any potentially carcinogenic substances in food. If I were given the choice of death today by accident, or death in 10–20 years by cancer, which would I choose? There is some chance—about 1 in 5—of dying by cancer from so-called natural causes. Alternatively, and indeed more likely in an accident, how would I rate a chance of 1 in 10 to 1 in 100 of immediate death or death within a short time through explosions or toxic gases, as against the same risk of death in 10 to 20 years? I would choose to live on.

It is believed that radiation presents new risks, but radiation has always been with us, and carcinogenic or genetic damage does not arise solely from radiation, as reported by Sir Edward Pochin¹. Apart from 'a different sort of hazard' from radiation, it was thought that accidents to nuclear sites might cause greater harm than hitherto accepted in modern society. In my view this is not so, and at this point I approach the nub of this present discourse, that is, how best or in what way to describe the results of a hypothetical accident to an industrial site?

In my early days in nuclear energy, it was customary to talk about 'maximum credible accidents' and particularly so in the USA, but in general so to circumscribe the conditions of the hypothetical accident as to make the 'mca' acceptable, so that the installation might be licensed. However, some writers describe accidents beyond those currently reviewed in the traditional 'mca' approach, as in the early document, WASH-740, describing in 1957 the possibility of 3,400 deaths and more than 10,000 injuries. Somewhat earlier, in 1955, at Geneva official papers described hazards from radioactive substances as one million to one thousand million times more dangerous than chemical poisons, whereas it is now generally accepted that plutonium is only about ten times more toxic than chlorine. This violent see-saw, from the trivial to the disastrous, has dogged the development of atomic energy. We need to come to terms with this situation. Perhaps both ends of the scale are possible and both represent half-truths, but we may penalise the further development not only of energy resources but also of our industrial and technological development unless we have a better understanding of the nature of hazards and their associated risk rates.

An accident in any major industry may lead to financial loss, the shutdown of plant; it may lead to no harm, or the same accident might cause many casualties. There is some chance of an accident occurring in most industrial installations or in transport. The consequences will depend upon many things: the quantity of toxic or explosive material available; the quantity released in the accident; the rate of release; whether the release occurs in seconds, minutes or hours; the surrounding population distribution; the conditions of wind and weather; topography; the effectiveness of remedial procedures on and off site.

Some of these are reasonably independent or capable of prior assessment. In many cases the accident is not caused by wind or weather, but the consequences may be greatly influenced by them. In some cases accidents are caused and may be predicted from unusual weather patterns—flood, high wind, low temperature and so on. In general, there is no clearly defined maximum; it is possible to derive more and more casualties by presupposing more unusual conditions—the limit or maximum remains vague and unapproachable. Yet this idea of 'worst' or 'maximum' cannot be too lightly discarded. In financial matters it is usual to have a defined limit of liability; by the same token it would be desirable to have an upper limit of hazard which may then be accepted or rejected.

Unfortunately this route is not yet open to us, and is certainly one not easy to follow. In recent history it has been the practice to describe the worst accident to reactors or to some industrial plants in terms of some framework of credibility, generally so framed as to make the consequences of the accident relatively small and not too difficult to accept.

There is another route—an alternative to the synthetic analysis of a hypothetical accident. This route is to list and survey the accidents which have occurred in certain fields—ground or air transport, petrochemicals, the manufacture of chlorine and so on—and to show that from some dozen or so accidents only a few people are killed. It is then fair to extrapolate to the future if the analysis takes account of any change in toxicity and quantity of material at risk and any improvement in the means for their control. Indeed, estimates prepared in this way give a good indication of the 'likely' results of an accident.

To return to 'the worst'. Until recently it might 'reasonably' have been said that the worst aircraft accident might kill 350 people. There was always some risk that two might collide and this has happened. It could be worse. USA studies reported in evidence to a Senate Committee⁷ have given a probability of an aircraft crash on Hollywood Park grandstand whilst occupied by a large crowd as about 10^{-3} per year and the chance of killing 100–10,000 as being in the range 10^{-5} – 10^{-7} per year. In this simple example, it could be that of two groups discussing risks in air transport, one could believe that 350 casualties represented the 'worst' whereas the other could fear the risk of 10,000 casualties.

An even greater range could apply to some industrial accidents. The accidental release of toxic or explosive gases has caused 10–20 deaths on several occasions. A retrospective analysis shows that in some cases, had the wind been blowing in another direction, the result might have been ten times worse. Furthermore, had the weather pattern been less favourable, the casualties would have been greater. It is known that under inversion conditions, with low wind speed, the downwind air concentration for a given release of material is up to ten times higher at a given distance than for average weather conditions, and that in the UK, inversion occurs about 15% of the time—a small chance, but still significant.

There has been considerable effort employed in assessing the chance of major hazards from man-made, or natural disasters, as from explosion, fire, earthquake, or even meteorite impact. These studies require a combination of two factors: extrapolation from past history weighted according to the judgment of the assessor; and the use of currently available data on probability of wind direction, weather category, population distribution.

Many small accidents have occurred, and will continue to occur, which kill from 1–10 people. There is some small chance that a combination of circumstances might cause the death of over 100 people. Rasmussen² and Okrent³ have explored a range of possible hazards in the USA and, for each of various categories of fire, explosion and so on, have given their prediction as follows:

Chance of killing more than 100 people:	10^{-1} – 10^{-2} per year
Chance of killing more than 1,000 people:	10^{-2} – 10^{-4} per year
For earthquakes, they estimate:	
Chance of killing more than 10,000 people:	$\sim 10^{-2}$ per year
And for dam failures:	
Chance of killing more than 10,000 people:	$\sim 10^{-3}$ per year
Their assessment for overall risk from all recognised sources gives:	
Chance of killing more than 1,000 people:	10^{-1} per year
Chance of killing more than 10,000 people:	in the range 10^{-2} – 10^{-3} per year

The situation in the USA is different from that in the UK. Natural hazards from tornadoes, dams and earthquakes are greater in the USA. On the other hand the UK population density is roughly 10 times that of the USA. My own view is that the comparable risk in the UK lies within a factor of 10 of the USA—perhaps a factor of 10 lower. But on this matter we should not be too complacent.

These figures may be frightening, and it would be terrible if 1,000 to 10,000 people were killed; it is unlikely, but it could happen and is experienced in other countries from earthquakes and floods. Even so, a single event of this type would barely change the overall accidental death rate in the USA or Europe. The overall accidental death rate is about 1 in 2,500 per year, although this is age dependent. Most of us have a 2% chance of accidental death in 50 years. In a country of 50 million people, this means that more than 20,000 die from theoretically avoidable accidental death (including suicides) each year.

In giving guidance on some new activity, there is need to take account of both current risk levels and public reaction but, in so doing, it is important that the public should be informed and that they should recognise the need for wise and balanced judgment in situations where absolute safety can no longer exist. The public seem to expect the experts to seek ways of reducing risk and if ways are discovered which promise clear benefit at not too great cost, they expect the remedy to be applied.

Additionally, I believe that there are pressures to reduce risk irrespective of the risk rate, or in the absence of specific knowledge of the risk rate. There will be pressure to reduce risks in atomic energy, in aircraft flight and ground transport, and in many industries, such as mining, fishing, chemicals, petrochemicals, steel, oil exploration; and also pressure to spend more money in medical research and health facilities as a means of reducing risk of suffering or death.

How best to resolve these pressures on money and skill? How best to decide whether to reduce risks still lower in places where they are already low, as against the need to reduce the frequent and relatively random causes of common accidents? There is no easy answer.

I believe that progress should be made in two directions: to improve communication between people on this matter of risk of hazards to life and the environment; and to continue to improve the techniques for the assessment of the risk of future harm to man and environment. A considerable effort is being deployed in both directions in the atomic energy field and is now being extended more widely in our industrial activities. □

Zoo story

Alastair Hay looks at the London Zoo, now experiencing some changes at the top

AT its Annual General Meeting this week, the Zoological Society of London (ZSL) was due to witness a major change in the composition of the Council, its governing body. Both the President, Prince Philip, and the Secretary, Lord Zuckerman, were resigning their offices, with Prince Philip leaving the Council altogether. The Council nominated Lord Zuckerman as President and Dr Ronald Hedley, the Director of the British Museum (Natural History), for the Secretaryship. The Secretary of the ZSL is the executive officer of the Council; when it was a salaried post in the years 1847–1943 it was one of the most sought-after positions by zoologists in Britain.

Three years after its inception in 1826—under the auspices of Sir Stamford Raffles (the first President) and the then President of the Royal Society Sir Humphrey Davy—the ZSL was incorporated by Royal Charter with the specific objects of “ensuring the advancement of zoology and animal physiology and the introduction of new and curious subjects of the animal kingdom”. Animal physiology at this time was concerned primarily with the optimal conditions for animal breeding. Thus, whereas Raffles was more interested in the scientific potential of the Zoo, Davy—in Raffles’ view—was more concerned with its “practical and immediate utility to the country gentlemen”.

Davy’s ideas notwithstanding, his support enabled the ZSL to develop rapidly into the centre for zoological discussion in Britain. In previous years the Linnean Society had been the hub of these discussions, although it was principally concerned with botany. There is some irony in the fact that the foundation of the ZSL was a reaction against this bias; the Linnean’s own development, in 1788 to cultivate “the science of natural history in all its branches”, was itself a reaction to the Royal Society’s own preoccupation with the physical sciences.

During its first hundred years the ZSL’s publications were mainly concerned with systematics, comparative anatomy, taxonomy and phylogeny. In this respect they very much reflected the interest of the Secretaries of the Society, men such as Philip Lutley Sclater (1859–1902) and Peter Chalmers Mitchell (1902–1935). But well before Sclater retired, the biological sciences were themselves undergoing rapid change. Zoology and animal phy-

siology were now sciences which required animal experimentation and a knowledge of genetics, biochemistry and endocrinology. The Establishment at the Zoo seemed to be unaware of these developments and consequently younger zoologists were looking elsewhere. The Society was losing the scientific support on which its integrity and very survival depended.

Huxley’s problems

Julian Huxley was the first of the experimental zoologists to be appointed Secretary. Although he attempted to change the Society’s approach to zoology he was, in the main, unsuccessful. By 1942 Huxley and the council were openly opposed to one another. Huxley resigned in 1943, an action which was regarded by many zoologists as a serious defeat for progressive scientists. For the next twelve years few changes were possible in the Society. The situation for the duration of the war and the first decade of post-war Britain required Huxley’s successors, Sheffield Neave and Lord Chaplin, to devote all available resources to restoration following bomb-damage and to the replenishment of the animal collections. Lord Zuckerman became Secretary in 1955 with the ZSL in a very poor state.

The ZSL received confirmation of its status as an educational charity in 1930. Lord Zuckerman believes implicitly in the importance of the Zoo as an educational institution and in the need for the Society to adhere to the terms of its Charter and his determination to institute changes along these lines and to bring it back into the mainstream of zoology involved him in a major clash with Fellows of the Society in 1957. At the Annual General Meeting that year he proposed, on behalf of the Council, an increase in Fellows’ subscriptions (unchanged for over 100 years), the creation of a new class of Scientific Fellow, and the extension of public visiting hours on Sundays.

The changes were essential if the Society was to preserve its charitable status and to increase its revenue. For many of the Fellows, however, these proposals represented a considerable challenge to their privileged status. As a result the 1957 meeting was probably one of the most lively in the Society’s history. The Council’s proposals were finally ratified, but not before the dispute was dragged into the High Court and finally settled in

Zoo guests

the Court of Appeal. The proposals and court ruling were incorporated in a new Royal Charter in 1963.

Ivor Montagu, one of the ZSL's Vice-Presidents and a regular visitor to the Zoo for nearly seventy years, believes that the 1957 proposals were absolutely essential for the Zoo's survival. In his view the strength of the institution lies in its Charter but the composition of the Council has sometimes made it vulnerable. He says it was set up in a way which grew alien to the world around it: the Zoo in its early days was very much a preserve of the gentry; a walk in the Zoological Gardens on Sundays by the Fellows and their friends was very much 'the thing to do'. The First World War altered the social climate and this, he says, forced the Fellows to relinquish some of their privileges. By pushing the 1957 proposals through, he argues, Lord Zuckerman "rescued the Zoo and brought it into the modern world." For many years London Zoo had indulged in the policy of 'stamp-collecting'—it had to have at least one specimen of each species. But with greater concern about conservation and the alteration in public attitudes that policy changed. The emphasis is now placed on maintaining fewer varieties of animals and these in viable breeding colonies.

Zoo activities

The ZSL is an institution which maintains the national collection of animals. It owns one of the most comprehensive zoological libraries in the world and is responsible for an extensive educational scheme which catered for 53,000 pupils in 1976. The Society publishes more scientific journals than even the Royal Society and

in addition it runs two research institutes of world renown. These activities, undertaken in addition to the normal display of animals, are financed in the main by gate proceeds. The ZSL's 1976 Annual Report states that with a turnover of some £2.5 million and a combined attendance of close on 2½ million at Regent's Park and Whipsnade, the Society had a year-on surplus of £179,000. But this sum, unfortunately, will have to be used to pay off the deficits accumulated in 1974 and 1975 when the effects of inflation and recession were sorely felt.

The additional activities undertaken by the ZSL are an obvious strain on the Society's revenue. Both in Britain and abroad many other institutions with far fewer responsibilities are in receipt of regular government subventions. London Zoo is not so endowed. The obvious question is whether it should be. Lord Zuckerman is circumspect with his answer. All he says is that the ZSL is as worthy of support as many of the institutions in regular receipt of public funds.

An intense debate is being conducted at the moment by the staff within zoos to decide their real purpose—the educational function of zoos, their role in conservation of endangered animal species, the nature of scientific research to be carried out and so on. The 1976 Report acknowledges part of that discussion. With its facilities the Society is well placed to become "an international centre for the scientific study of the problems of conservation." The Council proposes to combine the two research institutes, the animal hospital and pathology laboratory into an integrated 'Institute of Zoology'. The scientific expertise and support of the

new institute in reproductive physiology, biochemistry, immunology, radiology, parasitology and genetics "can put real knowledge behind attempts to breed stocks of rare animals". This is to become one of the institute's main projects.

Finance for conservation research, however, is very difficult to find. Many zoologists feel that at least some of the money raised for wildlife preservation generally could be used more profitably for the scientific research needed to back up the conservation programme. One organisation concerned with conservation is the World Wildlife Fund. Its Vice-President and Founder Chairman, Sir Peter Scott, feels that conservation is important in the context of zoos. He says zoos are especially important in two respects: for the captive breeding of species threatened by extinction, and for education. Zoos have a great responsibility to educate the young, he argues, and the ZSL has done well in both areas; although the Fund did not at the moment finance any conservation research at London Zoo, if a good case was made they "would consider supporting it".

The ZSL's total income in 1976 was about £12,000. Some 16% of this was spent on scientific activities. Today the proportion of income spent on research, publications and education stands at the respectable level of 18%.

Hedley's task

Ronald Hedley, the man succeeding Lord Zuckermann as Secretary of the ZSL, is a biologist by training with a background in chemistry, zoology, geology and physiology. His experience at the Natural History Museum should equip him well to deal with the public and with the scientific and educational functions of the Zoo; last week he said he was looking forward to the prospect of working with new colleagues there. But he is not approaching his new job with any preconceived ideas. Believing in the need to sample opinion, of which there will be no shortage at the Zoo, he intends to have a period of consultation first.

The Council of the ZSL has the ultimate responsibility for ensuring that the Society is successful. Dr Hedley as a member of that Council now has the two-fold task of involvement in the running of the Zoo and the Natural History Museum, which is an essentially complementary institution. He is conscious that the goodwill and support of their staff is essential for their continuing success, and takes up his post when the Zoological Society of London is probably more confident about its future than at any time in the past fifty years. □

As of this week Lord Zuckerman will preside over all the Zoo's affairs and chair any of its meetings which he attends. Previously, as the Zoo's Secretary, he had a more demanding task, which is one obvious reason why he might retire from the post. But, though now 73, he will still be around to offer advice, just as he has done in another capacity, that of a government science adviser. This link has lasted for the best part of 40 years, and culminated in promotion to Chief Scientific Adviser from 1964 to 1971. He is still to be found in and around the corridors of power.

Interviewed last week, Lord Zuckerman responded firmly to the suggestion that with the explosion of information no single individual could possibly advise over the whole spectrum of science. What was wanted of a scientific adviser, he argued, was an understanding of the "political, national and international" implications of technical decisions taken by governments; the immense political implications of President Carter's decision not to proceed with the breeder reactor, for example. That a political sense was required was particularly true

when all government departments already had specialist technical committees to consider long term planning decisions. Zuckerman says that "the idea of appointing a scientist just because he is a Nobel Laureate who has unravelled the structure of some particularly heavy protein molecule is nonsense. The idea of having the best mathematician is nonsense".

It needs no mathematician to calculate that Britain's Research Councils are now having a comparatively lean time. Zuckerman acknowledges that in the 1950s and 1960s he was one of the individuals who convinced people that science should be supported in a much bigger way and that now people have the right to enquire after the results of that policy. With the golden age of expansion over, some scientists will draw little comfort from his belief that they will just have to accept the cuts as a fact of life in a country as "hard-up" as Britain. But he believes the current period of belt-tightening will not restrict "real creative thought", and that there will be no long-term repercussions for scientific output.

Fiftieth anniversary of the Dunn School of Pathology

- 1 The Sir William Dunn School of Pathology
- 2 Dr Jean Medawar, Dr Anne Beloff-Chain, Lady Florey, Sir Peter Medawar, Sir Ernst Chain, Professor A. D. Gardner
- 3 Dr George Mackaness
- 4 Professor Dorothy Hodgkin, Professor D. Whitteridge
- 5 Professor Henry Harris

WHEN the trustees of Sir William Dunn's bequest offered to support the founding of a new pathology building in Oxford they stipulated that it should be fronted by flower beds. On 20 April, the occasion of the 50th anniversary of the opening of the Sir William Dunn School of Pathology, only the reminiscences of the plentiful past members of the School were more colourful and varied than the flowers outside. The celebrations were launched, in a style unequalled by later speakers, by Emeritus Professor A. D. Gardner. An Oxford graduate of 1907, Gardner recalled how Sir William Dunn's money, earmarked primarily to aid the destitute and the orphaned, came to be used for funding medical research. The School's first director was Professor Georges Dreyer whose strength, said Gardner, lay in his thorough statistical approach to research which was centred on the development of tuberculosis vaccines. His weakness lay in his belief that he was infallible—a vice, Gardner emphasised, that was unique neither to the man nor the era.

After Dreyer, in 1935, came Professor Howard Florey who was remembered in his pre-war days by Sir Peter Medawar for being exhilaratingly energetic and exasperatingly anti-intellectual. The war-time saga of the isolation and first therapeutic trials of penicillin by Florey's team was narrated by Dr Norman Heatley who emphasised the contributions of novel hardware (bedpans, biscuit tins and Russian butter tins) and novel,

hard-wearing female technicians. In 1952 when Henry Harris arrived from Sydney, Florey's direct interests in antibiotics were being wound up in J. L. Gowans' DPhil thesis. Thereafter antibiotic research was carried out under E. P. Abraham who told the story of cephalosporins from their bizarre origins in a Sardinian sewage outlet to the present day.

Florey's interests, ruled as ever according to Professor Harris by the illnesses with which he or members of his family were afflicted, turned to atherosclerosis, gastric secretion and inflammation. A three-pronged attack on inflammation was mounted by Florey through George Mackaness, Gowans and Harris who were to investigate the roles of the macrophage, the lymphocyte and the polymorph, respectively. Only Harris gave up. His decision that the polymorph had been good for a DPhil but would not do for a career brought out the fiercest in Florey. Harris was threatened with deportation to Australia, and communication between the two became confined to letters. Fortunately Harris's colleagues, particularly Abraham, rallied round and persuaded Florey to back down. Henry Harris survived to take over Florey's chair in 1963. We look forward to the 75th anniversary of the Sir William Dunn School of Pathology when tales of Henry Harris can best be told, perhaps under the shade of the ginkgo tree ceremonially planted by his wife on this occasion.

Peter Newmark

USA

The costs of high technology

A report last week on X-ray scanners has raised questions about expensive technology in the US health care system. Colin Norman reports from Washington

In mid-1973, a sophisticated and very expensive piece of medical equipment was introduced into the United States from Britain. Since then it has found its way into hundreds of hospitals and doctors' offices, and the swiftness with which the new technology has been adopted has generated a major controversy. This has helped shed light on the reasons why hospital costs have risen eight times faster than the cost of living during the past 25 years, and why many people despair that the American health care system can ever be brought under sensible cost controls.

The equipment, known as a computed tomographic (CT) scanner, is a nifty machine which its promoters claim will revolutionise the diagnosis of many medical disorders. Developed by EMI Ltd, the CT scanner is essentially a combination of an X-ray machine and a computer, which provides cross-sectional images of internal body organs. Early models were limited to use on the head, but later and more sophisticated versions can provide images of the internal organs of any part of the body. The scanner's advantage over conventional X-ray machines lies in its ability to produce high quality images of soft tissue structures from numerous angles.

Few people would quarrel with the argument that CT scanners represent a major advance in medical X-ray technology, or that they may be useful diagnostic tools in many instances. The controversy centres on the fact that the technology has been so widely and swiftly adopted in the United States that massive investments have been made before the clinical usefulness of the machines has been well documented.

Although less than four years have elapsed since the first CT scanners were introduced into the United States, an estimated 760 machines have now been installed or are on order. Since each machine has a price tag of between \$300,000 and \$700,000 and costs about \$300,000 a year to operate, hundreds of millions of dollars are being sunk into the technology by American hospitals. A particularly striking indication of the overwhelming demand for the machines is the fact that some 40 orders were placed for EMI's new whole body scanner before the machine

was even commercially available. By contrast, in Britain, where CT scanners were originally developed, only a handful of machines are in operation and fewer than 40 have been ordered.

This overwhelming and seemingly unreserved adoption of CT scanners in the United States led the Health Research Group, an organisation linked with the consumer advocate Ralph Nader, to charge last year that "the purchase of these machines is a particularly striking example of the introduction of extremely expensive medical technology into the health care system before there is adequate evidence that patient benefits or dollar savings exceed costs". The group demanded that a national moratorium be placed on the purchase of CT scanners until the benefits had been better evaluated. And last week, the Institute of Medicine, part of the National Academy of Sciences, said in a carefully worded report that "the long-term effects of CT scanning on medical care and its costs are not yet discernible".

The Institute's report, perhaps the most influential study yet published on the use of CT scanners, is noteworthy as much for what it says about the general problems of controlling hospital costs as for its recommendations about this particular technology.

The report is quick to acknowledge that CT scanners may have many important uses, and it lists some of the areas in which the machines may offer advantages over conventional diagnostic tools. Nevertheless, the Institute notes that conventional techniques may be just as effective and much cheaper in many cases, and "considers it essential . . . that controls be placed on the location and use of and charges for CT services". It also recommends that medical insurance companies should not pay for some types of CT scan until there is better evidence of their efficacy.

The question arises as to why the American hospital system has rushed to embrace CT scanners so wholeheartedly. The answer lies in the organisation and funding of the health care system, and the swift adoption of CT scanners epitomises many of the problems inherent in that system.

To begin with, there is little political incentive to hold down the costs of medical care in the United States. The middle classes, where political power largely resides, are generally well protected by private health insurance, and the medical costs incurred by the poor and the aged are met by the federal government. As the Institute puts it in

its report, "The growing share of personal health care expenditures covered by third-party reimbursement has reduced the incentives to control use (of expensive technologies), because the physicians decision to use services is separated from the patient's immediate expenses". According to officials in the Department of Health, Education and Welfare, more than 90% of the \$55,700 million hospital costs incurred last year were met by private insurance payments or federal Medicare and Medicaid schemes.

The report cites other reasons for the soaring costs, such as "competition among hospitals for medical staff, prestige, or revenues", and it notes that there has been a recent general increase in the use of diagnostic tests stemming partly from fear of malpractice suits, which "encourages defensive medical practice". All of these factors, the Institute states, suggest that "the present organisation of medical care and methods of financing and regulating that care in the United States have encouraged investment in beds and equipment beyond a socially efficient level".

Some states are trying to get a grip on soaring hospital costs through so-called certificate of need laws which require institutions to obtain approval from planning authorities before purchasing expensive equipment. But these laws, for a variety of reasons, have failed to curb the proliferation of CT scanners. The Institute report notes, for example, that some 15% of the CT scanners installed so far are located in the offices of private physicians, which are exempt from the certificate of need requirements, and "some physicians appear to have deliberately circumvented the intent" of the laws. In one well-publicised case, for example, after a hospital was denied a CT scanner, physicians at the hospital formed a partnership, bought a machine and installed it in an office across the street.

A final incentive for hospitals to purchase CT scanners seems to be their potential for generating revenues. The Institutes report states, for example, that the average charge for a scan is about \$240, and an independent economic survey of CT scanners published last year indicated that the average machine is used for about 3,000 scans per year. In other words, about \$700,000 is generated by each machine per year, more than enough to offset the purchase price and operating costs over a very short period.

Given that profit potential, there is some incentive for hospitals to use the machine in cases where less costly, conventional diagnostic equipment would

USA

● Total spending on research and development in the United States is expected to reach nearly \$41,000 million this year, according to figures compiled by the National Science Foundation. If the estimates are correct, support for research and development would stay ahead of inflation for the second year running, though the combined two-year increase would not be sufficient to wipe out inflationary losses incurred during the early 1970s.

According to the NSF study, the federal government is expected to spend about \$21,800 million in 1977, a 10% increase over 1976, while industry is expected to spend about \$17,500 million and about \$1,500 million will come from universities, non-profit institutions and so on. In terms of constant dollars, the total is expected to be about 6% below the peak spending years of the late 1960s. Measured as a proportion of the gross national product, spending on research and development has declined steadily since 1964.

NSF has also published an estimate of the number of scientists and engineers employed in 1976, which suggests that after four years of growth, the scientific labour force now numbers 542,000. The total is about 20,000 below the 1969 level, however. Some 40,000 science and engineering jobs were lost during the 1969-1973 cutbacks, NSF reckons.

● While the nuclear industry in the United States was licking its wounds last month, following President Carter's decision to defer commercial reprocessing and to downgrade the breeder reactor programme, a report on nuclear power plant security drew some fresh blood. Published by the General Accounting Office (GAO), an investigatory agency of the Congress, the report concludes that "security systems at perhaps all power plants would not be able to

withstand sabotage attempts by threats that are now considered minimum by (the Nuclear Regulatory Commission)".

Based on inspections of security systems at six power plants, carried out by GAO investigators, the report is written in uncharacteristically blunt language, laying blame at the doors of both the nuclear industry and NRC. It states that though the quality of security forces seems to vary greatly from plant to plant, some deficiencies were encountered on each inspection. The faults included lack of training of security guards (as little as four hours at one plant), high turnover of security personnel (up to 48% a year), and poor security equipment. In particular, the report cites the following two horror stories:

We accompanied an NRC inspector to one power plant at night. The inspector asked the guard manning the guardhouse to aim a closed circuit television camera on a particular spot. The guard tried but was unable to work the system. The inspector opened a door which rang an alarm in the guard house. After waiting several minutes, the guardhouse was called to find out why no one responded to the alarm. A guard in the guardhouse answered that all of the available guards were too busy.

At yet another site, we asked a guard about the locations of certain critical systems of the plant, including the control room. He told us that the guard force knew nothing about the location of these systems because the guards were not allowed inside the power plant.

Although the NRC has recently published a set of new regulations designed to increase the effectiveness of security systems at nuclear plants, the regulations are not due to come into effect until August 1978. The GAO report says that although the new regulations are "on the right track", NRC should take steps immediately to ensure that operating plants are made more secure.

Colin Norman

serve just as well. To try to limit such potential abuses, the Institute recommends that medical insurance companies should establish an advisory committee to develop criteria for paying CT scan charges. It also recommends that requests for use of CT scans should be reviewed by a physician with responsibility to control access to the machine, who would determine whether the scan is appropriate.

The central question here is not whether CT scanners are useful, but what level of investment can be justified and how the machines should be allocated and managed. Those are questions that the American health

care system finds difficult to address, given its fragmented nature, the competition between hospitals for revenues and prestige and the third-party payment system. As Dr Harvey Fineberg, Director of the Graduate Program in Health Policy and Management at Harvard School of Public Health put it last week, "The fundamental assumption that we in this country have not yet made is that the pot of resources available for health care is limited . . . if you ask whether CT scanners are useful, the answer would be 'yes', but if you frame the question 'would they be a sound investment', you may come up with a different answer". □

WEST GERMANY

Energy plan published

Werner Gries reports from Bonn on the energy research programme recently approved by the West German government

THE main emphasis of the German federal government's DM 6,200 million energy research programme for 1977 to 1980, published at the end of last month, is on nuclear research, but the rational use of energy, progress in coal technology and the development of new energy sources are also prominent. Details of the programme, which marks the first time the state has intervened to bring together systematically both nuclear research and work on other energy resources, are as follows:

Nuclear energy will take some 75% of the state funds. Fast breeder and high temperature reactors remain the first priorities in the country's nuclear power programme, but research and development work is to continue in the fields of uranium enrichment, reprocessing and the disposal of radioactive waste. A state subsidy of about DM 1,200 million will be needed just to complete the prototype power stations now under construction to house the breeder and high temperature reactors. Reactor safety is a key aspect of the programme; R&D on nuclear-powered ships will be continued only on a fairly modest scale, receiving about DM20 million annually.

Rational energy use: Around DM100 million annually will go into research into technologies for rational energy use. Attention will be given to techniques of remote heat supply, reverse cycle heating systems, heat recovery processes and the use of waste heat from power stations.

Coal technologies: R&D in coal technology, one of the most important aspects of the non-nuclear side of the programme, will receive increasing amounts of funding, amounting to an average of DM140 million annually. Coal gasification, improvements to coal-fired power stations to reduce pollution, coal liquefaction and improved mining techniques will all receive support.

New energy sources: The government will support the development of new sources of energy to the tune of DM130 million a year on average, with the focus on nuclear fusion (about DM90 million annually) and on solar energy. In the government's view, solar energy is of interest in West Germany only as a means of heating build-

ings and providing hot water, and research is being concentrated in this area. Further work on nuclear fusion is dependent upon the site of JET; the Research and Technology Minister, Hans Matthöfer, expressed his hope for an early decision on this.

It is Herr Matthöfer's ministry which has much responsibility for R&D in West Germany. Its budget in 1977 of DM4 million million compares with total research expenditure in 1977 estimated at DM26 million million. Federal research programmes are designed for a period of about four years, classified by sectors and provided with a corresponding budget during the planning stage. The energy programme is one of ten programmes for

sectors that also include data processing, marine research and technology, raw materials, electronic components, space and aviation, and so on.

The outlines of the new energy programme were determined by the federal government following a cabinet resolution. The programme is not immediately binding for industry but outlines the frame of what the government considers essential. The country's primary energy consumption in 1975 broke down as follows:

Mineral oil	52.1%
Hard coal	19.1%
Soft coal	9.9%
Natural gas	14.0%
Nuclear energy	2.0%
Others	2.9%

The structure of energy consumption differs from the United States and other large countries. A breakdown of energy consumption by sectors in 1975 shows that industry consumed 35.9%, transport 19.7% and domestic 44.4%. In the government's opinion the largest savings have to be achieved in the domestic sector. Industrial energy consumption, related to national product, has actually stagnated for about ten years.

An output capacity of 33,000 MW from nuclear power stations in Germany was anticipated for 1985, but a maximum of only 25,000 MW can be expected because of recent breakdowns in power stations and the postponement of various building projects. □

SWEDEN

● A report recently published by Sweden's National Environment Protection Board shows that the business of making polluted lakes clean is slow and difficult. Sweden has 100,000 lakes covering 9% of the country's surface, and of these about 15% in the southern third of the land are being overloaded with phosphates and nitrogen. In general, the polluted lakes are victims of acid rain, sewage, industrial effluents and agricultural run-off. Recovery programmes are having limited success.

In the long term, acidity will be reduced only if fuels can be burned without releasing much sulphur into the air; but as a stop-gap measure, lime has been spread onto the lakes themselves in some severely-affected areas. Prospects for large-scale liming seem poor, however, not only because of the cost but also because the traces of toxic metals found in most commercial lime would become significant in the quantities involved.

Another recovery tactic has been to cut off flows of effluents into a lake and the streams feeding into it. This has only improved water conditions slightly, as the lakes' internal circulation of nutrients has not been affected enough to cut down the production of plankton to acceptable levels. Reducing pollution by treating sewage to remove the nutrients from it is not always effective either: although it caused plankton levels to go down in one case, the gains were partly offset because the farmers in the area increased their use of nitrogen fertiliser.

In some cases, causes and effects in the pollution cycle are impossible to determine. The fact that the burbot in Lake Vättern has decreased dramatically in the past ten years while its main prey species has increased could be due to the burbot's

high PCB content or simply to over-fishing. But once the balance between the two species has been upset it may never be re-established, and the reason for the change may never be known. Pike in Lake Vänern are black-listed because they contain mercury from industry at the northern end of the lake. The fact that they have been fished less has meant that their average size has grown, which has resulted in increased cannibalism and a slower growth rate in their population. In these circumstances it is extremely difficult to say exactly what the direct effects of mercury pollution on pike may be.

With these uncertainties, recovery programmes are hard to design. The report gives the impression that the problem would be easier to tackle by prevention rather than cure.

● The Nuclear Fuel Supply Company has reached an agreement with the French firm Cogema under which spent nuclear fuel from the Barsebäck 2 and Ringhals 3 reactors will be reprocessed at the French facility in La Hague. Cogema will accept spent fuel produced until the end of 1979, and will return it after reprocessing to Sweden for final storage. Because of delays in the Ringhals 3 programme, it seems likely that the spent fuel sent will in fact come only from Barsebäck 2.

Under the law specifying the conditions to be met by reactor operators before the government will give permission for the building and operation of nuclear power plants, the owners of Barsebäck 2 must organise secure reprocessing of spent fuel. In their opinion the present agreement fulfils their obligation. Sweden's Energy Minister, Olof Johansson, who is trying to stop Sweden's march into the nuclear society, is refusing to admit

defeat. He says that the government can decide whether the owners have met the conditions only after it has examined the contract. The government's pronouncement is expected to be made by 1 October.

● According to a recent statement by the Minister of Education, Mr Jan-Erik Wickström, Sweden may be facing an acute shortage of people educated in technology and the natural sciences. The 1970s, said Mr Wickström, have seen difficulties in recruiting students to technical and natural science lines at both secondary and tertiary levels. He blamed this partly on the state of the labour market, which was unfavourable for natural science graduates at the beginning of the 1970s, partly on the evident inability of primary schools to exploit students' interest in natural sciences, and partly on the unpopularity of technicians and scientists in a society affected by the green wave.

A look at the official statistics hardly clarifies the picture. It is true that the number of students reading natural sciences and mathematics at tertiary level fell by 25% between 1971 and 1976. But that should be seen against a background of a general drop in interest in tertiary education: the number of students reading humanities and social sciences, for example, fell by 20% during the same period. Yet these years saw the number of students at institutes of technology increase by 9%. A similar pattern holds for doctoral degrees taken over the same period: down by 16% for mathematics and natural sciences, down by 17% for humanities and social sciences, but up by 5% for technology.

Wendy Barnaby

IN BRIEF

Nuclear study

In a declaration issued at the end of the two-day summit meeting in London at the weekend, the leaders of the world's seven leading non-communist industrial nations committed themselves to increasing nuclear energy to "help meet the world's energy requirements" and announced the launching of an "urgent study" (a "preliminary analysis, to be completed within two months", according to an annex) on how to do this while reducing the risks of nuclear proliferation.

The announcement, one of the main features of the final declaration, was carefully worded to smooth over the differences that have emerged within the western alliance since President Carter began acting on his worries about international trade in nuclear technology for ostensibly civilian purposes.

The proposed committee is expected

to consist of experts from the various countries and the study, on uranium supplies and aspects of the nuclear fuel cycle, will decide the terms of reference to be followed for a broader study lasting perhaps a year. Though it will be difficult for any such committee to agree conclusively, particularly in so short a time on what is now so political a matter, the key point is itself political, namely that the study represents a review of nuclear policy at the highest possible political level.

Geos update

Initial testing of experiments on board ESA's research satellite Geos has now been completed; all were working well early this week. Final operating conditions were due to be achieved by mid-week when the long radial booms would be fully deployed to 20 m. The booms had been at 2.5 m, giving a rather high spin rate for the particle

experiments. The slow drift of the apogee to longitude 37.7°E was halted on 8 May and Geos is now in an orbit with apogee conjugated to Northern Scandinavia, but a limited programme of correlated measurements will be possible.

The satellite is in view on every second 12-hour orbit for nearly 8 hours per day and the viewing time is well matched to the period during which the altitude is greater than the 3.5 Earth radii where all experiments can operate. The viewing time could be doubled by collecting data from the other orbit using NASA ground stations in Alaska, but the apogee remains at the same local time. It will be next February before the local time of the apogee moves from early evening through the day to probe the night-side region of the magnetosphere.

NASA's investigation into the failure of the launch vehicle continues. A detailed report is expected this week.

ON 30 April the blown-out Ekofisk Bravo oil well in the middle of the North Sea was finally capped, having spewed 12,000 tons of oil into the sea in the previous nine days. Three days later the oil, constantly tracked by satellite, had virtually disappeared. Such a startlingly anti-climatic ending to a drama billed as an ecological disaster must leave a few people somewhat puzzled as to where it all went.

A good deal of it of course went upwards. The UK Department of the Environment in *Accidental Oil Pollution of the Sea* (Pollution Paper no. 8, 1976) estimates that up to 40% of the relatively light North Sea oil may evaporate in one day; oil from the Ekofisk field has an even lower specific gravity than the North Sea average. The volatile fraction fortunately includes the most toxic components of the oil, the aromatic hydrocarbons such as benzene and toluene.

What was left after evaporation and solution formed that water-in-oil emulsion known as 'chocolate mousse' whose persistence normally causes great despondency. But in this case, probably again because of the lightness of the oil, the emulsion was an unstable one, quite easily dispersed by the rough seas which had conveniently developed soon after the well was capped. The silver sheen slick of dispersed oil droplets covered a huge area for a short time, but by the middle of last week was reduced to a few square miles.

Once the oil had been broken down into small droplets the paraffins could be digested by bacteria. Some particles are ingested by zooplankton which die and fall to the seabed, making the oil available to the more abundant bottom-living bacteria. The

Where goes the oil?

BACKGROUND

enormous amount of extra carbon available will cause short-term changes in the community but probably no long-term disruption. Though normally one would expect some tar to be formed from the heavier residues there may be virtually none from the Ekofisk oil.

Nature was responsible for 90% of the oil dispersal; the rest was managed by the Norwegians, who contained the oil with booms and

managed to skim 1,000 tons off the surface. A better figure probably could not have been hoped for: removal of the oil is certainly the ideal solution to the pollution problem but present equipment, being ineffective when waves are more than 7-foot high, is useless for most of the time in the very rough North Sea. The clean-up ships were fortunate in this case to get two days of near calm to pump most of the thicker patches of oil off the sea.

By yet another happy chance the blow-out happened at such a time as to cause minimal damage to fisheries and birds. The Ekofisk field is in the middle of Norway's valuable mackerel fishing ground; mackerel do not swim near the surface but their eggs, which are laid during May, float near the surface and would certainly have been damaged if the blow-out had happened three weeks later. The Norwegians are reluctant to use chemical dispersants on oil because of their toxic effects on marine life. In this case they were proved right by the rapidity with which the oil disappeared but there would have been strong pressure to use chemicals if the accident had happened in July, when large numbers of auks are swimming across the North Sea from Scotland to Norway.

Thus, apart from a few unanswered questions, for example concerning the long-term effects of hydrocarbons in food chains, there is cause for great relief. Things may not work out quite so well next time.

CEGB change

The retirement of Sir Arthur Hawkins as chairman of the UK Central Electricity Generating Board (CEGB) at the end of last week has raised the prospect of an early resolution of the problem which the proposed Drax B coal-fired power plant poses. The issue is not whether it should be ordered, but when. That depends in the first instance on electricity demand, but other factors have intervened.

The plant was planned for 1979. The turbine and boilermaking industries face a lean time with demand down and want the order brought forward; the government's 'think tank' has recommended a rationalisation of the industry and this is still under discussion. The CEGB has said the order can be placed now, but wants compensation from the government. What is in dispute is the amount of that compensation, and who should pay it. The hope is that with the departure of a key

figure in the growing controversy, some new formula can be found to satisfy Glyn England, the new CEGB chairman. With the visit of Mr Benn, the Energy Secretary, to Moscow this week for talks with Mr Kirillin, his Soviet counterpart, no announcement is expected before next week.

On the move

Dr Frederick Horner is to take over from Dr J. A. Saxton as Director of the Appleton Laboratory near London. Horner joined the Radio Division of the National Physical Laboratory in 1941, which has since evolved into the Appleton Laboratory. In 1969 he became Deputy Director. Most of his research has been concerned with finding radio direction and studying radio emissions from thunderstorms. Since 1950 he has been involved in international radio affairs and has held office in international organisations. Saxton retires on 1 July.

The UK Department of Health will soon be losing its Chief Scientist, Sir Douglas Black, following his election as President of the Royal College of Physicians. No replacement has been announced.

WHO message

The World Health Organisation (WHO) should strive to achieve a universal level of health conducive to high social and economic productivity by the year 2000. This was the message of Dr H. Mahler, Director-General of the WHO, when he presented his report for 1976 to the World Health Assembly in Geneva last week. He said that the WHO should through its country health programming promote development in primary health care and appropriate health technology, even though in so doing it might meet with opposition from the medical and various allied professions and industries.

In Britain, most western European countries and the United States, the so-called 'organic movement' is growing. Its members believe that 'natural' manures, derived from animal excreta or composted vegetable matter, are better than factory-made chemical fertilisers. The movement embraces those with widely different views. The more extreme believe that chemical fertilisers poison the land and those who eat its products. The more moderate consider that organic manures improve the structure and fertility of the soil better than do inorganic fertilisers, and produce crops which differ nutritionally in subtle ways from those grown with liberal dressings of artificials. They claim that pests and diseases are less rampant when organic techniques are used, though they admit that the highest yields are often obtained with balanced dressings of inorganic fertilisers and the liberal use of chemical pesticides. In general they claim quality rather than quantity for organic produce.

As an entomologist on the staff of Rothamsted Experimental Station, on whose fields the classical experiments demonstrating the value of chemical manures were performed, I was at first very sceptical. However, when, over twenty years ago, I visited the experiments of the Soil Association at Haughley in Suffolk, and examined the long-term experiments set out and organised by Lady Eve Balfour, I decided that this work needed to be looked at critically and scientifically. I did not have an experience like St Paul on the road to Damascus, with an instant conversion, and I found

some of the explanations of organic farmers and gardeners hard to accept, but I did think that this unique long term study, where comparable fields were receiving different fertiliser and pesticide treatment, ought to be thoroughly investigated.

I attempted to interest bodies like the Agricultural Research Council,

Muck is magic

KENNETH MELLANBY

who were at that time comparatively generously supplied with funds to support research. I could not persuade them to part with a penny to investigate the work at Haughley, or to study organic methods generally. Time and time again my advances were rebuffed. Even when I got together a Research Advisory Committee, which included hard-headed

scientists from the chemical industry, no government money from agricultural research funds was forthcoming. In fairness to the ARC and my former colleagues I must admit that they believed that the subject had been thoroughly studied by established methods, and it was not unreasonable to assume that little more was to be discovered. Furthermore, some of the extreme organic fanatics talked such evident nonsense, and their more rational colleagues suffered by association.

Today things seem to be different. I was delighted to see a headline in the *Times* recently which read "Ideas of organic farming being taken more seriously", and to discover this referred to a lecture by a member of the staff of the ARC. Not long before I heard my former colleague Dr G. W. Cooke, recently the distinguished head of the Chemistry Department at Rothamsted and now also with the ARC, admit that modern work had shown that organic manures were now being found to increase some crop yields much more than would have been expected from an analysis of the inorganic nutrients present.

I hope that this will mean that organic methods will now be really critically studied, as I proposed so long ago. If the ARC sees the light in this way, they may wish to follow the example of the now-defunct Council for Scientific Policy. This body prefaced its last report with an extract from the General Confession in the Book of Common Prayer. I suggest that the ARC choose as its text Luke 15, v. 7.

'The Selfish Gene'

SIR,—Lewontin's review of Dawkins' book *The Selfish Gene* (17 March, page 283) is a disgrace. It fails to meet any of the standards of informative value, objectivity and fairness to the views of others that are part of the code of science. That it is a very biased review is reasonably evident to anyone reading it; unfortunately a reader unacquainted with the controversy which is its background may well be left with the impression that, even setting aside obvious unpleasantness in the review, the book itself probably is unsound and not worth reading. This is a great pity since in fact the book is not only the best existing outsider's introduction to a new paradigm and a new field of knowledge but, in its overview of the situation and in many original details, is itself a significant contribution to this field.

For its intellectual worth, and seemingly in motivation as well, Lewontin's outline of the book is on par with Bishop Wilberforce's notorious attack on Darwin and Huxley at the British Association meeting of 1860. It would be easy to defend the book and reply to the review point by point, but this would be an unpleasant, muck-raking task, and it would be difficult to avoid matching rhetoric against rhetoric and so bringing debate to the plane where Lewontin wants it to be. Against such a review I feel justified in following Huxley to give a very subjective assessment of my own but wish to avoid trying to match the wit of the historic reply to the bishop.

Whether the literature of socio-biology reflects an ignorance of the difference between "properties of sets

and properties of their members" or "confusion between materialism and reductionism" are matters about which I feel little concerned. On the other hand I feel a warmth very far from indifference when I encounter in most of the literature in question signs of a spirit which I share and which I have always assumed is the same as that which motivates scientific enquiry in all its branches. I can most simply express this spirit by calling it a desire to understand and communicate the nature of the world. I find it present in full measure in *The Selfish Gene* and totally absent in Lewontin's review.

Yours faithfully,
W. D. HAMILTON

Imperial College Field Station,
Ascot, UK

Efficient fish

SIR,— "... fish are not efficient users of food materials other than animal protein and fat", according to Dr Purdom and Mr Preston (31 March, page 396). This is incorrect for some species. At Reading we routinely obtain feed conversion ratios of less than 10 kilograms of fresh vegetation to 1 kilogram of fish when feeding ryegrass (*Lolium* spp.) to grass carp (*Ctenopharyngodon idella* Val.). This represents a protein conversion efficiency of 40%. Equally efficient conversion of terrestrial vegetation is recorded in the literature for *Tilapia melanopleura* Dumeril and *Tilapia zillii* Gervais in pond culture. The figure of 100 to 1 given by Purdom and Preston is applicable to a diet of aquatic vegetation which consists largely of water. Moreover, we have evidence which suggests that leafy ter-

restrial vegetation provides all the major nutrients required to support rapid growth rates in grass carp.

If it is assumed that ryegrass for artificial drying costs £6 per tonne fresh weight, the feed cost is 6p per kilogram of fish produced. Feed costs could be reduced by using agricultural by-products and food-processing wastes. It should therefore be technically possible to farm fish intensively and at low feed costs. Farmed herbivorous fish are rated highly as food throughout much of Asia, Africa and Eastern Europe.

Yours faithfully,
J. C. J. DOMANIEWSKI

Value of textbooks

SIR,—During recent discussions on the structure of the living cell at meetings of the Physiological Society, the Anatomical Society, the Biochemical Society, and the Royal Microscopical Society, several participants have made the remark "Surely, you don't believe what is written in text books". This viewpoint seemed to be held by several other participants at the meetings. This raises such fundamental questions of scientific truth, that we wonder if any of those who support this view might be prepared to justify it in print. We should say that we were grossly disturbed by such a suggestion and thoroughly disagree with it.

Yours faithfully,
H. HILLMAN
P. SARTORY

Competition 13

(From an idea by Martin Rees). In the next few years we discover—never mind how—that there is intelligent life nearby in the universe, but that we are more 'advanced' than they. A prize of £10 is offered for the best short message to their equivalent of

Isaac Newton, or any other character from our history, telling him what scientists are up to these days. Send entries by 15 June to the Editor, and mark envelope Competition 13.

Competition 12 asked for fatuous, actual or fictitious professorships. Honourable mention to Drs Haslam and Haslam for the fictitious Chair of Wind Engineering in the Medical Faculty (to go with a new journal entitled Wind Engineering) and the actual Chair of Artificial Intelligence.

But the prize to Professor V. Trimble (Irvine) for the following:

It would be difficult to top Cambridge's own (real) Plumian Chair of Astronomy and Experimental Philosophy, whose incumbent, we presume, is required to go about kicking stones and looking for trees in quads where there is no one about to observe them. Recent interest has, however, also been attracted by Brown University's (fictitious) chair of Psychoceramics, whose present holder, Professor Carbury, is, of course, an expert on cracked pots. My own university's English department has contemplated a chair in Historical Metallurgy to be reserved for someone learned in the study of Old Saws.

news and views

Cosmic gamma-ray bursts

from K. J. Orford

SINCE their first reported discovery 4 years ago, cosmic gamma-ray bursts have been observed at a rate of roughly one per month. These events have until now been observable only from satellites, or balloons, since the weak gamma-ray energy flux cannot penetrate the atmosphere or compete with atmospheric radiation. Their theoretical interpretation has been hindered by a lack of sufficient knowledge of their celestial positions, their distribution in size, and a lack of any correlated phenomena which could narrow the search for sources. As a consequence the number of theoretical models has exceeded, if not the number of bursts (about 50), then at least the number of well established parameters. Some recent results reported in *Nature* may help.

Manchanda and Ramsden (*Nature* 266, 425; 1977) point out that about 90% of the bursts have sizes, or energy fluxes, within a relatively narrow range. If the assumption is made that they all originate in explosive events of similar energy output then a burst's size reveals its distance, at least relatively. The distribution in distance so obtained bears a remarkable resemblance to the distribution of supernova remnants. Supernovae are thought to be sources of both neutron stars and black holes. The disruption of a neutron star by a black hole would provide a neat explanation not only of the size distribution, but also of the gamma-ray burst's energy spectrum. Two consequences of this theory are that the bursts should have a particular distribution in celestial position and that very small and very large bursts should be relatively infrequent. The first must await the accumulation of a large number of bursts with well measured positions, easy only for the rarer large bursts which are recorded by several satellites. The second is in contrast with the situation for many random astronomical phenomena, for which the count rate is in some way inversely dependent on size, that is,

smaller bursts would be expected to be more frequent. Smaller bursts are indeed observed to be less frequent, but unfortunately just at a size where current satellites have difficulty in detecting them.

To resolve this, a number of balloon-borne experiments have been carried out with very large detectors. Such detectors, some hundred times larger than those at present carried in satellites, should be capable of seeing bursts about two orders of magnitude smaller in size. Their lack of confirmed observations has enabled some upper limits to be placed on small burst rates, with consequences for burst origins (for example Carter *et al.* *Nature* 262, 370; 1976). However Cline *et al.*, at the Goddard Space Flight Centre, have revealed a source of confusion for such experiments (*Nature* 266, 694; 1977). In an attempt to detect very small bursts, and to prove that any bursts seen were of cosmic origin, two similar detectors were flown on balloons separated by at least 1,400 km. They achieved 20 h of simultaneous observations, but detected no coincident bursts of cosmic gamma rays. Slow 'bursts' were observed on each individual payload and some were associated, but separated in time by many seconds. Whatever the cause of these (suggested to be due to magnetospheric activity), they constitute a serious source of background noise for burst experiments using a single balloon or near-Earth orbit satellite. As these authors point out, much more sensitive experiments are needed to enable small bursts to be seen and their expected anisotropy to be observed.

It may be that the theoretical interpretation of bursts may be helped more immediately by the observation of some correlated phenomenon. One particular burst was observed on 16 August last year by one of the chain of Vela satellites responsible for the original discovery, by two new satellites, Solrad 11A and 11B (Laros *et al.*, this issue of *Nature*, page 131) and by a transatlantic balloon experiment. The gamma-ray results published do not by themselves mark out the burst as very special (except as a simul-

taneous observation by a number of different experiments, including a balloon flight). However, what may be a very significant radio observation was made by Mandolesi *et al.* (*Nature* 266, 427; 1977) at Medicina and Trieste. They observed on 16 August 1976 a radio burst at three widely spaced frequencies at Medicina, and at a fourth frequency using a 10-m parabola at Trieste. All lasted about 30 s, the duration of the gamma-ray burst, and they rule out man-made, atmospheric and solar effects as its cause. It occurred less than one minute after the gamma-ray burst, to which coincidence they ascribe a chance probability less than 10^{-4} . If the satellite burst position is eventually found to agree with the radio position, it will confirm the first such burst-correlated phenomenon. The separation in time would then be a consequence of the evolution of the burst source and would limit the models proposed to explain both bursts. Since this coincident radio burst was discovered only about a month after full operation of the radio array, and if the two bursts had a genuine common source, then one may hope that further coincidences will soon follow. □

A hundred years ago

THE WOODPECKER.—In the April session of the German Ornithological Society Prof. Alton concluded the recital of his investigations on the habits of the woodpecker. The peculiar drumming sound often caused by it was shown on various grounds to be entirely disconnected with the search for insects as hitherto supposed, and was regarded as a call to the opposite sex. Dr. Brehm defended the woodpeckers against the charge of seriously injuring the trees, and considered the slight damage resulting from them as more than compensated by the colour and animation which they gave to the otherwise sober and quiet forests.

Sequencing DNA

from Maria Szekely

It is somewhat unusual that a new technique should already be being used all over the world at the time of its publication, but this is exactly what has happened with the ingenious new method of DNA sequencing worked out by A. Maxam and W. Gilbert at Harvard University. The method is now described in full detail (*Proc. natn. Acad. Sci. U.S.A.* **74**, 560; 1977), but already DNA sequences established in this way have been published—by Walz *et al.* (λ promoter-operator region (*Nature* **262**, 665; 1976)), by Fiers' group (SV40 DNA (*Cell* **9**, 117; 1976)), by Musso *et al.* (control region of the *gal* operon (*Proc. natn. Acad. Sci. U.S.A.* **74**, 106; 1977)), by Sures *et al.* (histone genes (*Cell* **9**, 495; 1976)) and others, showing how a useful technique can spread at amazing speed among scientists working in this field.

DNA sequencing, which some years ago seemed a formidable task and was approached by trying to convert it to an RNA sequencing problem (Gilbert and Maxam themselves sequenced the *lac* operator in 1973 (*Proc. natn. Acad. Sci. U.S.A.* **70**, 3581) by transcribing it into RNA and determining the sequence of this transcript) is today a relatively simple operation which can be accomplished by routine methods much more quickly than RNA sequencing could ever be done. In fact, the present trend is to convert RNA sequencing problems into DNA sequencing tasks to speed up the work.

Two very efficient techniques are available today to establish DNA sequences: Sanger's 'plus and minus' technique (*J. molec. Biol.* **94**, 441; 1975), based on enzymatic copying of single-stranded DNA, the spectacular results of which have recently been published in *Nature* (see **265**, 687; 1977) and Gilbert and Maxam's technique based on chemical modification and breakdown which has been applied to a variety of double-stranded DNA fragments. Both methods have in common a very convenient and fast way of interpreting the data: the sequence can be read off the gel electrophoretic pattern obtained from a complete mixture of different sized fragments. This readout technique makes it possible to establish long sequences in one experiment; the longest nucleotide stretches which can be analysed are in the range of 100–150 nucleotides and

the upper limit depends only on the resolution attainable in the gel electrophoresis.

The basic principles of the two methods are quite different however. Sanger, in the 'minus' technique, copies a single-stranded DNA stretch, synthesising different length fragments, each of which ends before a given base. Running four parallel samples in which stoppages occur at different bases provides sufficient information to read the sequences of the whole DNA fragment. The 'plus' technique serves to confirm the sequence; here the fragments are degraded by making use of the exonuclease activity of T4 DNA polymerase, under conditions when this degradation stops at sites where a given base is present. Again, four samples are run in parallel to determine the positions occupied by all four bases in the DNA fragment.

In the technique of Gilbert and Maxam no copying is involved, nor any enzymic reactions. Chemical reagents are used to modify and excise a given nucleotide from the polynucleotide chain. If conditions are mild, only partial modification occurs and only about one in 50 or 100 nucleotides is excised. In a random mixture there will be fragments of different lengths ending at all possible positions where this base was present. Four parallel samples are prepared also in this method to locate the positions of all four bases along the DNA chain.

In many cases either method can be used successfully for DNA sequence determination. The choice of the appropriate technique depends mainly on the single or double-stranded nature of the DNA. Sanger's technique requires single-stranded DNA whereas the Gilbert–Maxam procedure works equally well with single and double-stranded molecules. One variant of the Gilbert–Maxam procedure involves denaturation of the DNA fragment and separation of the strands, this step can, however, be omitted and another strategy used instead; the 5'-termini of a double-stranded DNA fragment can be labelled and the fragment split in the middle. This treatment yields two smaller fragments in each of which only one strand carries a labelled group. Consequently, only the products from this strand will show up on the autoradiographs. This represents a great advantage, as strand separation may prove difficult when applied to longer DNA molecules (although the Gilbert–Maxam separation method seems to work very well for restriction

fragments). As to the length of the DNA molecule to be sequenced, the Gilbert–Maxam technique has been mainly used so far for determining the sequence of restriction fragments and is probably best suited for fragments 100 to 200 nucleotides long. In the plus and minus technique, copies of any desired length can be synthesised from a convenient and well-defined start point, irrespective of the length of the DNA template. The method has also been used on the intact complete genome of ϕ X 174 phage (Sanger & Coulson *J. molec. Biol.* **94**, 441; 1975). The start point is determined by the oligonucleotide used for priming the synthesis of the labelled copy and can thus be chosen more or less at will.

Apart from the very great progress in elucidating the structure of different genomes, these techniques may well prove of great advantage in the field of RNA sequencing. Complementary DNAs have already been produced for sequence studies on eukaryotic mRNAs (see for example Proudfoot *J. molec. Biol.* **107**, 491; 733; 1976 and Cheng *et al. ibid.* 527). These cDNAs may now be accessible to the new sequencing techniques. We may expect in the near future a great advance in the sequence analysis of this group of mRNAs which are of great functional importance but which so far have presented serious problems for sequence studies. □

Man-made auroral pulsations

from Alan Johnstone

PULSATING auroras are one of the most intriguing types of auroral display. Irregularly shaped patches of light appear to turn on and off regularly with a period of the order of 10 s. The beam of electrons, which produces the auroral light when it strikes the atmosphere, must be modulated by some plasma wave, on its way down the magnetic field line from the outer radiation belt. Despite much speculation about the cause no satisfactory explanation has been found. The report

Maria Szekely is a lecturer in the Department of Biochemistry at Imperial College London.

Alan Johnstone is at the Mullard Space Science Laboratory at University College London.

An important control on the immune response in many animals, including rodents and primates, appears to be provided by the immune response (Ir) genes which are tightly linked to the major histocompatibility complex (MHC). These genes are antigen specific in their effects, that is, they appear to play an important part in determining whether an animal can respond to any particular antigen, but as yet their function and site of action is still unclear. However, evidence is rapidly accumulating that the Ir genes are in fact expressed in macrophages or the macrophage-like cells that process or present antigen to T lymphocytes.

Rosenthal and Shevach (*J. exp. Med.* **138**, 1194, 1213; 1973) showed that guinea pig T cells from an F_1 hybrid between a responder and a non-responder could only be stimulated to proliferate by antigen-coated responder (or F_1) macrophages, but not by non-responder macrophages. Subsequently, analogous proliferative studies have been performed in the mouse by Schwartz and his colleagues (*J. Immun.* **117**, 531; 1976 and *Proceedings 3rd Ir Gene Workshop*, Asilomar, 1976). These studies suggested that the proliferating cells recognised antigen in association with macrophage Ir gene products, which since they were inhibited by anti-Ia antisera (antisera directed against the I region-associated antigens of the mouse MHC) were probably macrophage Ia antigens. While the immunological role of the proliferating cell(s) in these assays is not known, analogous results have been obtained in assays for the induction of antibody (Pierce *et al.* *J. exp. Med.* **144**, 371; 1976) or of helper cells (the T cells which collaborate with B cells to enable the latter to produce antibody). For example, Erb *et al.* (*Eur. J. Immun.* **6**, 365, 1976) have demonstrated the capacity of macrophage Ia

Marc Feldmann is an ICRF research fellow working at University College London.

Are the Ir genes expressed by macrophages?

from Marc Feldmann

antigen, complexed to a fragment of immunogen, to form a soluble complex of molecular weight ~55,000 daltons, which replaces intact macrophages in the induction of helper cells. All these studies reinforce the concept that there are Ir gene effects expressed in macrophages. J. E. A. P. Miller and his colleagues have recently obtained compatible results in a delayed hypersensitivity (DTH) model in the mouse, leading to the same conclusion for the Ir genes involved in DTH (Miller *et al.* *J. exp. Med.*, in the press).

In this issue of *Nature*, Rosenthal, Barcinski and Blake (page 156) extend this point. Using insulin molecules from various species, with minor differences in amino acid sequence, they demonstrate Ir gene control of antigen recognition at the level of the macrophage, measured by the proliferative response of guinea pig T cells. Their results are most easily interpreted by postulating that macrophages may select the appropriate portion of the antigen to be presented to T cells. How is this done? The simplest possibility is that macrophage Ir genes define a class of receptors of broad specificity that 'focus' or orient antigen for T cells to recognise it. Conceivably, these receptors may be the descendants of the recognition molecules which antedate the vertebrate immune system. If that interpretation is correct the antigen-presenting cells, and not the T cells, dictate the antigen specificity of the Ir gene effect. But since T cell responses depend so intimately on macrophage presentation, macrophage Ir genes would reveal them-

selves (as has been found) as defects of T cell function. The search for the immune response gene products may then already be partly over—they have been isolated and partly purified as the macrophage Ia antigen-immunogen complex, which induces the activation of helper cells *in vitro*.

The idea that the Ir genes are expressed on macrophages is also compatible with other findings that have been interpreted quite differently. Munro and Taussig for example (*Nature* **256**, 103; 1975), described two types of mice with genetically determined low responses to the synthetic polypeptide (T,G)-A-L; those which did not make T helper factor (an antigen-specific mediator of T cell help) and which was interpreted as a T cell defect, and those which did not respond to T cell helper factor, which was interpreted as a B cell defect. But since macrophages are needed for both these reactions a macrophage defect could be at the root of both these failures. T cell suppression has also been proposed as a mechanism of non-responsiveness and since suppression is much less dependent on macrophage function than T cell help, a net suppression would occur in the presence of dysfunctional macrophages. This idea is not incompatible with the proposed role of the macrophage.

Whatever the truth of the mechanism of Ir gene action, it now seems certain that macrophages and macrophage-like cells have a more complex role in the immune system than hitherto suspected, and the precise nature of the antigen-presenting cell needs to be re-examined. Are these classical macrophage or lymphocyte-like cells, or a hybrid between the two. In view of the plethora of lymphocyte subpopulations recognised in the past two years, the existence of yet another type of cell in the immune system need not be too improbable. However, the question still remains as to whether there are Ir genes expressed by other cells of the immune system.

that pulsations have been induced artificially near a pulsating display is unexpected and might give valuable insight into the mechanism causing the natural phenomenon.

The artificial pulsations were found by Deehr and Romick (this issue of *Nature*, page 135) in one of the natural auroral spectral lines at 200 km altitude, just below a barium release in the F region of the ionosphere. This technique, in which 1.5 kg of Ba is ejected by a thermite reaction from a canister carried aloft by a rocket, is used to measure electric fields and

winds in the upper atmosphere. The barium cloud is partially ionised by sunlight, forming a cloud of ions which resonantly scatters purple light from the Sun and a neutral cloud which scatters green light. The neutral cloud is blown across the sky by winds while the ionised cloud is driven by the combination of electric fields and winds. By tracking both clouds optically from the ground the effects of the two forces can be separated. The technique is very effective and has been used many times in the last decade.

Ideally, the barium should not dis-

turb the medium it purports to measure. Small barium releases, such as that used by Deehr and Romick, do not distort the electric fields seriously although they must have some effect. Their observation is not the first of perturbations in the ionosphere beneath a barium cloud. Stoffregen (*J. atmos. terrest. Phys.* **32**, 171; 1970) detected a temporary increase in the auroral line at 557.7 nm at 100 km altitude below a barium cloud. He did not observe pulsations and there was apparently little natural aurora present. Spracklen and Jones (*Q. Jl R. Astr.*

Soc. 17, 469; 1976) have observed an increase in E region (100 km) electron densities by radio techniques. Both authors have attributed this coupling between the F region where the barium was released, and the E region where the disturbance is observed to the flow of charge from one side of the cloud to the other to neutralise the build up of a polarisation electric field as the cloud starts to move. The horizontal current, across the magnetic field, can only flow in the E region where there is sufficient Pedersen conductivity to allow it. The downward flow of electrons from one side of the cloud enhances the electron density in the E region while the upward flow on the other side should leave a lower density.

The release reported by Deehr and Romick is the only one to take place within a significant amount of natural aurora and its presence seems to be a necessary condition for the pulsations. They were observed at 200 km where electrons of 500 eV deposit most of their energy. Higher energy electrons would penetrate further into the E region, but any effects there might have been were masked by natural aurora.

Natural pulsating auroras are found

predominantly at altitudes below 100 km (Brown *et al. Geophys. Res. Lett.* 3, 403; 1976) implying that higher energy electrons, between 10 keV and 60 keV, are usually involved. Bryant *et al. (Planet. Space Sci.* 23, 867; 1975) measured the electron fluxes producing pulsating aurora directly and also found relatively high energy particles. Further, they were able to detect phase differences between the pulsations observed at different energies, with the higher energy pulsations seen first. This velocity dispersion placed the source of the modulation more than 40,000 km away, and certainly not within 300 km.

The differences between what is known of natural pulsations and the circumstances surrounding the observations of the artificial ones seem to suggest that the existence of the two displays side by side was coincidental. It would be hasty to draw such a conclusion when so few hard facts are known about either phenomenon and when the range of possible mechanisms is still so wide. One thing is certain—there will be determined attempts to repeat the observation during future barium release experiments wherever they are performed. □

It seems likely that complex interactions between peptidergic neurones will be uncovered since neurones originating in dorsal root ganglia and separately containing Substance P and somatostatin enter the spinal cord where they overlap with neurones containing enkephalin, neurotensin and TRH. Peptide-monoamine interactions also seem likely in view of the high density of enkephalin- and Substance P-containing neurones in areas containing cell bodies for serotonin, dopamine and noradrenaline. Iversen reported experiments that indicate an inhibitory control of Substance P release by GABA, and raised the possibility that these putative transmitters represent excitatory and inhibitory controls respectively for dopaminergic mechanisms in the basal ganglia. This may have important consequences in our understanding of various disease states such as Huntington's chorea and Parkinson's disease.

New results and controversy still abound in the opioid peptide field. The potent analgesic and behavioural effects of β -endorphin are the subject of considerable research (D. de Wied (University of Utrecht) and D. G. Smyth (National Institute for Medical Research, London)) and now it seems that stable analogues of enkephalin produce similar effects, even on intravenous administration, according to reports by R. Miller (Wellcome Foundation) and A. Z. Rónai (Budapest). Unfortunately there is little evidence yet that these short chain peptide analogues will prove to be less addictive than morphine. A promising note was sounded by L. Terenius (University of Uppsala) who described the possible anti-schizophrenic action of the opioid antagonist naloxone in Swedish patients, thus implicating endorphins in some mental disease state. Caution was sounded here, however, by the report that American psychiatrists had failed to reproduce these results. Terenius also finds increased levels of endorphins in the cerebrospinal fluid of schizophrenic patients and results in this area may prove easier to replicate than in the more problematic area of the clinical assessment of schizophrenic remissions. A further link between analgesia and endorphins was reported by Terenius and J. Hughes (University of Aberdeen) who both found increased opioid peptide levels in the cerebrospinal fluid of patients receiving intracerebral brain stimulation for the relief of chronic pain.

The major impression left by this symposium was the impressive accumulation of evidence for central peptidergic transmission but the lack of evidence relating to defined physiological roles. However, most par-

Centrally active peptides

from John Hughes

A symposium on Centrally Active Peptides, organised by the Biological Council, was held at the Middlesex Hospital Medical School, London, on 4-5 April, 1977.

AN extra dimension has been added to neurobiological research in the past few years with the recognition of the potential importance of peptide-releasing neurones in the brain. The concept of peptidergic neurotransmission and neuromodulation has reached fruition as an area of multidisciplinary research which promises major advances in our understanding of normal and abnormal brain function.

Important advances in the distribution of peptides were reported and the great value of immunohistochemical techniques in this field was emphasised. A picture emerged of an extensive distribution of peptidergic neurones throughout the brain and spinal cord. Prominent amongst these are neurones containing Substance P and enkephalins; these systems seem to rival and perhaps exceed that of the better known catecholamines. A significant advance has been the demonstration of

cell bodies for peptidergic neurones (R. P. Elde (University of Minnesota), S. H. Snyder (Johns Hopkins University) and L. L. Iversen (MRC Neurochemical Pharmacology Unit, Cambridge)). It seems that the enkephalins are contained in short interneurones with a terminal distribution closely paralleling that of opiate receptor binding sites. This system appears to impinge on areas receiving primary sensory inputs as well as on those involved in the control of respiratory, cardio-vascular, somatic motor and neuroendocrine functions.

Iversen presented cogent evidence for a central neurotransmitter role for Substance P, and this peptide is now a firm favourite as one transmitter involved in the relay of information by small primary afferent sensory fibres. Multiple transmitter roles for Substance P also seem likely from its distribution in other areas such as the basal ganglia, hypothalamus and limbic system. Other neuronal systems containing vasopressin, oxytocin, vasoactive intestinal peptide, thyrotropin releasing hormone (TRH), somatostatin and neurotensin have also been identified in many brain areas (Elde, M. J. Brownstein (National Institute of Mental Health, Bethesda), A. G. E. Pearse (Royal Postgraduate Medical School, London) and Snyder).

John Hughes is Deputy Director of the Unit for Research on Addictive Drugs at the University of Aberdeen.

ticipants seemed confident of finding further evidence for the participation of peptides in normal and abnormal brain function. Continuing research is likely to lead to a deeper understanding of neuronal physiology with corresponding therapeutic benefits. □

Membranes and receptors

by Peter Newmark

A conference on Receptor-Signal Transmission was held in Titisee on 30 March–3 April, 1977. It was sponsored by the Dr Karl Thomae GmbH, a subsidiary of Boehringer-Ingelheim.

A CLUSTER of receptorologists, convened for three days in the Black Forest, pondered not only the mobility of receptors but also the transmembrane activation of adenylate cyclase, mechanisms of cell adhesion and membrane changes in secretion.

The presentation of a ligand to its receptor may be an event of considerable complexity involving cooperative effects whereby the initial binding can either promote or hinder further binding. One of the best examples of this is the negative cooperativity demonstrated in the binding of insulin to its cell surface receptors. P. de Meyts (National Institutes of Health, Bethesda) was cautious in his discussion of the mechanisms of negative cooperativity. He has however obtained evidence that the avian insulin receptor still exhibits negative cooperativity when solubilised. The solubilised receptor exists in high molecular weight form in the absence of insulin, and is converted, reversibly, to low molecular weight form by addition of insulin. From that de Meyts suggests that negative cooperativity, often supposed to be the result of clustering of receptors, instead involves the dissociation of a high affinity tetramer form of the receptor to a low affinity monomer. de Meyts has also been looking for negative cooperativity with a series of insulin analogues and the results, interpreted in conjunction with the known three-dimensional structure of insulin, indicate that cooperativity is determined by a discrete domain on the surface of the insulin molecule distinct from that involved in binding.

A highlight of the meeting was the general, probably unprecedented, agreement that emerged from the various contributions on the molecular inter-

actions involved in the transmembrane activation of adenylate cyclase following the interaction of ligand with receptor (M. Rodbell, NIH, A. Levitzky, University of Jerusalem, E. Helmreich, University of Wurzburg and M. Schramm, University of Jerusalem). All agreed that the receptor is not physically coupled to the adenylate cyclase moiety and that the activation of the enzyme as a consequence of the ligand interacting with its receptor is a GTP-dependent process. The GTP, whose origin is intracellular, is thought by Rodbell to activate both the receptor and the adenylate kinase each by way of a separate nucleotide binding site. Levitzky favours the view that only the enzyme is activated by GTP. That the GTP activation is normally transient and is terminated by hydrolysis of the nucleotide is shown by the permanent switching on of adenylate cyclase by GTP analogues that resist hydrolytic degradation. Some progress was reported in the purification of the relevant GTP binding proteins (Rodbell and Helmreich) and of both the β -adrenergic (Levitzky) and epidermal growth factor receptors (C. F. Fox, University of California, San Francisco).

From the general agreement that

there was no direct, permanent association between receptor and enzyme, it can be predicted that a receptor from one cell should be able to couple functionally with the adenylate cyclase from another cell when the two cells are fused. Schramm reported experiments which bore out that prediction. In initial experiments (*Proc. natn. Acad. Sci. U.S.A.* **73**, 4410; 1976) Friend leukaemia cells, which do not possess β -adrenergic receptors, were fused with turkey erythrocytes which had been pretreated with N-ethylmaleimide or heat to inactivate their adenylate cyclase (not their receptor as mistakenly stated in *Nature* **265**, 681; 1977). Ghosts of the fused cells exhibited a low basal adenylate cyclase activity that was markedly activated by the β -adrenergic drug isoproterenol. Since then equivalent results have been obtained with mixtures of quite different cell types. For example the β -adrenergic receptor of rat C6-glioma cells can be coupled with the adenylate cyclase of mouse Y-1 adrenal tumour cells. What is more the affinity of the receptors for various agonists is unaltered after being coupled to a foreign adenylate cyclase.

I. Pastan (NIH) reported a series of studies that have led him to the view

Multinucleon transfer reactions

from P. E. Hodgson

MULTINUCLEON transfer reactions are now used extensively to study nuclear structure, and recently a group at Los Alamos has found remarkable similarities between the spectra of states excited in the same final nucleus by the ($^6\text{Li},d$) reaction on the one hand and by the (t,p) and (h,n) reactions on the other (*Phys. Rev. Lett.* **38**, 587; 1977).

The group measured the ($^6\text{Li},d$) reaction on ^{56}Fe , ^{57}Fe , and ^{58}Fe for excitation energies up to about 4 MeV in the final nuclei, using a lithium beam of 34 MeV. About 20 states are known in this region of excitation for these nuclei, and it was found that only a few of them are excited by this reaction, and with few exceptions these are just the states also excited by (t,p) reactions going to the same final nuclei.

The exceptions are the O^+ states at about 3.5 MeV in each of the final nuclei that are excited by ($^6\text{Li},d$) but not by (t,p). These are very probably the states strongly excited by the (h,n) reaction, and interpreted as two-particle two-hole pairing vibration states in the $Z=28$ proton closed shell.

The group therefore concludes that the ($^6\text{Li},d$) reaction is sensitive to the same neutron and proton pairing correlations that govern the correspond-

ing two-nucleon transfer reactions.

This conclusion supports recent work on the alpha-particle spectroscopic factors, in which the four-particle amplitude is factored into coupled two-nucleon structure factors. The similarity between the ($^6\text{Li},d$) and (t,p) reactions is then explained as the transfer of the proton pair to the ground state and the neutron pair to the ground and excited states as in the (t,p) reactions. The similarity between the ($^6\text{Li},d$) and (h,n) reactions is explained in the same way.

This work suggests further experiments on the two- and four-particle transfer reactions to determine the spectroscopic factors and to relate them to the details of nuclear structure. It also shows that the ($^6\text{Li},d$) reaction can be used to study two-particle excitations that cannot be studied directly by two-particle transfer reactions because the requisite target nucleus is unstable. Such studies should also shed further light on the alpha-particle spectroscopic factors that are important for the study of alpha-clustering in nuclei.

P. E. Hodgson is in the Department of Nuclear Physics at the University of Oxford.

Peter Newmark is the Biological Sciences Editor of Nature.

that the altered growth characteristics of transformed cells are dissociable from their altered phenotype (used here to mean low adhesiveness, rounded shape, increased surface microvilli and lack of microfilament bundles). One line of evidence comes from a mutant Swiss 3T3 cell line that has a normal phenotype at 39 °C but which adopts the transformed phenotype at lower temperatures in conjunction with a rapid fall in cyclic AMP levels. Further evidence comes from a mutant Balb/C 3T3 cell line which is defective in the synthesis of N-acetyl glucosamine. It has normal growth properties but a transformed phenotype. When the defect is circumvented by the addition of N-acetyl glucosamine the phenotype reverts to normal. Finally there is evidence that the addition of a major cell surface glycoprotein (CSP or LETS) to transformed cells, which cannot themselves synthesise it, results in a reversion to normal in phenotype without any effect on the growth properties of the cells. Pastan concluded that a reduction in cyclic AMP or cell surface glycoproteins causes the transformed phenotype but that the abnormal growth of transformed cells has a separate and dissociable cause.

Jockusch (Biozentrum, Basle) discussed the possible role of microfilaments in the movement of secretory vesicles from the interior of the cell to the surface. At 25 °C but not at lower temperatures the microfilaments show a preference for attaching to chromaffin granules with the "correct" polarity were they to have the functional role suggested. S. Morris (Max-Planck-Institut, Göttingen) has also used chromaffin granules in his studies of the membrane changes associated with secretion. By freeze fracture he showed that intramembraneous particles (IMP) were not present in areas where inter-granular contacts had been made under the influence of calcium ions. Electron microscopy showed that the sites of granule contact were characterised by a pentilaminar membrane structure.

Whereas Morris's system is but a model for secretion since no plasma membrane is present and no secretion occurs, M. Raff (University College, London) reported comparable results in degranulating mast cells. He showed that the contacts between plasma and granular membranes were characterised by a pentilaminar structure and that these sites neither contained IMP nor could be labelled by ferritin-tagged lectins or antibodies. Since protein displacement was seen before membranes had come into position Raff raised the possibility that the proteins are laterally displaced before fusion and subsequent secretion. That sequence

of events was in part disputed by B. Satir (University of California, Berkeley) whose own observations of mast cell degranulation are consistent with her long series of studies on secretion by ciliated protozoa. In both cases the secretory vesicle has an array of IMP which at least in the protozoal systems, attaches to a complementary array in the plasma membrane. Satir considers that the displacement of the IMP only takes place after fusion has begun and furthermore she has never observed a pentilaminar membrane structure where granular and plasma membranes are in contact.

The release of histamine from the mast cell is triggered by IgE acting by way of the transient opening of a calcium gate (Raff). So is one of the two mechanisms of 5-hydroxytryptamine triggered secretion from the insect salivary gland (M. Berridge, University of Cambridge) whereas the other mechanism uses cyclic AMP as the second messenger. W. Loewenstein (University of Miami) presented evidence that any calcium entering the cell is rapidly sequestered close to its point of entry and would not be able to diffuse into adjoining cells through gap junctions. He also reported experiments, using a series of fluorescently-labelled molecules of known size, which provided data consistent with the idea that the pores in the gap junctions are about 15 Å in diameter, easily large enough to allow the passage of cyclic AMP. That is not to say that cyclic AMP either does or can pass through the pores:

The phenomenon of cell-cell adhesion was dealt with by several contributors. U. Rutishauser (Rockefeller University) has used a novel strategy in looking for a cell surface product that controls the reaggregation of dissociated chick embryo retinal cells. Starting with a heterogeneous antibody to retinal proteins he has found a protein fraction in retinal cell culture supernatants that prevents the inhibitory action of the antibody on cell adhesion. So far a 500-fold purification has yielded an active fraction that still contains three major proteins. The same factor(s) seem to be present on the surface of other solid tissues sug-

gesting that there is no tissue specificity in that component of the process of cell aggregation. M. Steinberg (Princeton University) also believes that "you can go a long way with one kind of glue in tissue morphogenesis". His views are based on the hierarchical sorting out of mixed pairs of any six tissues or of pairs of the same tissue but taken at different stages of embryonic development. The pairs of tissues do not separate on sorting out but one forms a compact core around which the other wraps itself. Steinberg proposes that in every case the core tissue simply has a greater cohesiveness than the wrapper tissue. Since cohesiveness can be roughly equated with surface tension Steinberg has attempted to measure the 'surface tension' of the various tissues by measuring the shape that an aggregate of each tissue adopts under centrifugal force. The results are uniformly consistent with predictions. From all of which Steinberg concludes that tissue morphogenesis can be controlled simply by the inherent cohesiveness of different tissues at different times without the need to invoke specific aggregation factors.

On the other hand L. Glaser (Washington University, St Louis) sticks to the view that there are specific molecular determinants of cell adhesion since he can mimic the cellular adhesion seen with various neuronal cell lines, with their plasma membrane preparations.

The mechanisms underlying the topographically ordered projection of retinal neurones onto the optic tectum of the mid-brain were discussed by S. Roth (Johns Hopkins University). It was R. W. Sperry who first proposed that the projections were determined by specific chemical affinities between each neurone and its site of synapse formation. A more elaborate version of that idea proposes that there are two complementary chemical gradients on retinal and tectal surfaces, one in the anterior-posterior direction, the other in the dorsal-ventral direction. In looking for evidence of the latter gradient Roth has developed a technique in which dorsal retinal cells can be shown to adhere preferentially to ventral tectal halves and *vice versa*. Recently he has found that the ganglioside G_{M2} inhibits this assay and that G_{M2} liposomes behave like dorsal retinal cells in adhering preferentially to ventral tectal halves. He also reported that G_{M1} synthetase, for which G_{M2} is a substrate, is the only enzyme of 30 tested that is more concentrated in the ventral than the dorsal tectum. Although Roth has not yet been able to detect the predicted reverse distribution of G_{M2} in the tectum, it does look as though he

has evidence of an asymmetric distribution of a possible molecular recognition system.

Is this the first toe-hold in putting the process of retino-tectal pattern formation on a firm biochemical footing? Or is it a futile exercise that cannot hope to explain the complexities involved? We all went home! □

Positive ions in the stratosphere

from L. Thomas

OBSERVATIONS of ion composition with rocket and satellite-borne mass spectrometers have made a major contribution to our understanding of the ionised regions of the upper atmosphere but have been restricted to heights above 60 km because of experimental difficulties. In the lower part of the height range the relatively high ambient pressures make it necessary to use a high speed pump for maintaining the spectrometer within its operating pressure range, and the small ion concentrations give low signal currents. Another complication encountered in the rocket observations at these lower heights has been the fragmentation of weakly bound ions through thermodynamic break up at the shock front associated with the supersonic velocity and in collisions, because of the electric fields required to draw ions into the sampling orifice. The difficulties are accentuated at still lower heights because of the greater atmospheric pressures and the increased rocket velocity. Consequently, for stratospheric levels, information is available only from ion mobility measurements but these cannot be used to identify the different ion species present.

F. Arnold, D. Krankowsky and K. H. Marien of the Max-Planck-Institut für Kernphysik, Heidelberg, have developed a quadrupole mass spectrometer with a cryogenically cooled pump, an improved sampling procedure, and a relatively low draw-in potential to reduce the effects of ion fragmentation and, thereby, have managed to extend ion composition measurements down into the stratosphere. They have reported three sets of rocket measurements over the height range 35–55 km (*Nature* **267**, 30; 1977). Although the mass resolution was limited to 2 a.m.u. to ensure sufficient sensitivity, the authors have been able to make a tentative identification of the ions registered. Above

about 40 km the most abundant ions were found to be consistent with proton hydrates, $H^+(H_2O)_n$, with n ranging from 1 to 3. It has been known for more than a decade that such hydrates dominate the positive ion composition over the height range 60–85 km in normal conditions, although some doubt still exists about the appropriate value of n in the ambient ions. Below 40 km, the present results show that a marked change in the predominant ion species occurred within a height range of a few kilometres, and the authors have interpreted the ion masses as resulting from reactions of the proton hydrates with minor neutral species; these species are required to have a higher permanent dipole moment or proton affinity than water to permit the replacement of water molecules or proton transfer to occur. On the basis of aeronautical arguments and supporting laboratory data Arnold *et al.* propose formaldehyde as the neutral species involved. This is known to be a major product of the oxidation of methane, a constituent whose height distribution is reasonably well established. The concentrations of formaldehyde estimated from the interpretation of the ion composition measurements are consistent with those derived in photochemical models (see for example Stewart & Hoffert *J. atmos. Sci.* **32**, 195; 1975). It seems likely that fragmentation has occurred in the ion sampling and, consequently, the particular proton hydrates and formaldehyde-based ions are probably not truly representative of stratospheric conditions. However, as the authors point out, it might be expected that the fragmentation will have removed water and formaldehyde molecules without modifying the central ions.

At stratospheric heights ionisation is produced by the interaction of galactic cosmic rays with atmospheric gases, the primary ions produced being those of molecular oxygen and nitrogen. The formation of proton hydrates from these ions is well understood from laboratory measurements and numerical studies of the ionospheric D region (Ferguson *Rev. Geophys. Space Phys.* **9**, 997; 1971). It would be expected that the ion chemistry of the stratosphere would involve minor neutral species in addition to water, because of the greater variety and concentrations of these species at these heights. In this connection, the inference concerning the upper limit on ammonia concentrations drawn from the absence of relevant ions is of interest. The value quoted is rather smaller than would be expected from loss by photolysis alone (McConnell *J. geophys. Res.* **78**, 7812; 1973) and could indicate the rapid loss of ammonia by collisions with, or con-

version to, aerosol particles.

Considerable interest is currently being shown in the chemistry of the stratosphere. This has arisen out of concern about the catalytic depletion of ozone by chlorine atoms produced by the photodissociation of chlorofluoromethanes (CFMs) transported from the Earth's surface (Rowland & Molina *Rev. Geophys. Space Phys.* **13**, 1; 1975). The observations of ion composition are relevant to the question of whether ion-molecule reactions might play a significant part in the loss of the chlorine-bearing compounds. At the height of the observations reported, the CFMs will be photodissociated and attention needs to be concentrated on the photodissociation products, namely chlorine atoms, chlorine oxide and hydrogen chloride. No exothermic reactions are known to occur between proton hydrates and these three gases (Fehsenfeld *et al. J. geophys. Res.* **81**, 4454; 1976) but the corresponding information relating to the ions identified below 40 km is not available.

Apart from the immediate considerations of environmental protection, the study of the stratosphere has become an active area of atmospheric research. It seems certain that mass spectrometer techniques for the measurement of ion composition will be exploited both in rocket and high-altitude balloon flights. The measurements will serve to complement the observations of neutral minor constituents which are being pursued vigorously and are also likely to inspire further studies of ion-molecule reactions. □

Whither protein structures?

from S. D. Dover

THE pipe-dream of designing and producing a protein to carry out a specific task has been brought nearer reality by the advent of recombinant DNA which offers the possibility of isolating, mutating and cloning particular genes. The resulting change in amino acid sequence specified could produce the intended structural change in the protein. But this will only be possible with an adequate theory of the effect of sequence changes on structure, based firmly on experimental structural information. Without this theory at the level of atomic detail,

S. D. Dover is a lecturer in the Department of Biophysics at Kings College London.

L. Thomas is a member of the staff at the SRC Appleton Laboratory.

designing new structures would be a hit-or-miss affair.

Interest in the solution of the problem of analysis and, subsequently, prediction of protein structure from sequence has an extensive history. From the studies of Ramachandran (*J. molec. Biol.* **7**, 95; 1963), to those of Levitt (*Nature* **261**, 552; 1976; *J. molec. Biol.* **104**, 59; 1976) theoretically oriented work has been progressing. The basic data for these studies have been the protein structures which regularly appear in the literature. The problem has tended to be approached from the point of view of overall structure with atomic details being left until later.

This has been partly due to the fact that most protein structures available are unrelated. Of the related structures the globins are probably the ones likely to reveal the greatest comparative information. The overall picture of haemoglobin and its allostery has been described by Perutz. Not only is there an abundance of species and within-species mutant haemoglobins of the four-chain type, but also single chain oxygen carriers such as haemerythrin (*Proc. natn. Acad. Sci. U.S.A.* **72**, 2160; 1975), erythrocrucrin (*Eur. J. Biochem.* **19**, 42; 1971) and the monomer/dimer system of the sea lamprey (*J. molec. Biol.* **74**, 331; 1973). Consideration of the chain interactions in atomic detail is likely to be stimulated by recent refinement of sperm whale myoglobin.

Takano (*J. molec. Biol.* **110**, 533, 569; 1977) has just published the first refinement of the deoxy- and met-structures since Kendrew *et al.* (*Nature* **190**, 666; 1961) first interpreted their map. Using new diffractometer data and variants of the well-tried method of alternating phase and realspace refinement (*Acta Cryst.* **A27**, 436; 1971) structures suitable for detailed comparison with haemoglobin were achieved. Takano's stereo diagrams show rather clearly the similarity of structure despite the differences in sequence. The possibility of extensive comparisons of this type is most encouraging, but it does raise a number of problems. Should one compare only whole myoglobin molecules or also separated sections of the chain? How can one objectively make the comparisons between non-identical objects and quantify and display the comparisons?

The relationship between haemoglobin and myoglobin provides information at all levels, but the relative changes are greater than one might want for truly secondary structure. As a starting point movements smaller than those produced by a single amino acid change would be interesting. Such movements would be expected to occur immediately before denaturation, even

though it is a cooperative phenomenon. Stability studies on haemoglobin have already been started (see *Nature* **247**, 341; 1974; *Nature* **255**, 256; 1975). Extension to full crystallographic refinements with crystals at, for example, different pH and ionic strengths might be the key to a number of problems associated with small atomic movements. But will there be PhD students to do all those structures? □

Heat flow at the mantle surface

from Peter J. Smith

SOME time ago Chapman and Pollack (*Earth planet. Sci. Lett.* **28**, 23; 1975) took what they called "a new look" at the Earth's thermal characteristics, producing in the process the first worthwhile map of the global surface heat flow. Then, as now, there were still large areas of the world with few or no data; but Chapman and Pollack had hit upon the idea of filling these gaps with heat flow values predicted from known empirical relationships between heat flow and tectonic age. Both real and predicted observations were then incorporated into a 12th degree spherical harmonic analysis which was translated into a global contour map.

Pollack and Chapman (*Earth planet. Sci. Lett.* **34**, 174; 1977) have now extended their analysis to the much more difficult problem of plotting the heat flow at the crust-mantle boundary. Mantle heat flow is, of course, the total heat flow less that produced or released in the crust; but it is not easy to determine just what the crustal contribution is. Most heat produced in the continental crust comes from the decay of radioactive isotopes whose concentration decreases with depth in some only vaguely understood way. Most heat from the oceanic crust, on the other hand, is released as the lithosphere produced at oceanic ridges cools, although there is also a small but significant radiogenic component.

Combining theory with experimental results, Pollack and Chapman nevertheless manage to estimate these crustal contributions to the total heat flow, whence they derive sufficient data to carry out an 18th degree spherical harmonic analysis. The resulting global contour map of heat flow at the mantle

surface differs from the corresponding crustal surface map in two notable respects. First, a comparison makes it clear that the near equality of continental and oceanic heat flows at the Earth's surface does not extend down to the mantle; at the crust-mantle boundary the mean heat flow in continental regions is only about half of that in oceanic regions (28 mW m⁻² and 57 mW m⁻², respectively). This means that the mantle below the oceans must be considerably hotter than that beneath the continents as several theoretical models have already suggested (see for example, MacDonald *Rev. Geophys. Space Phys.* **1**, 587; 1963).

The second result is that there is much less heat flow contrast within continental regions at the mantle surface than there is at the crustal surface. In Australia, for example, the mean crustal surface heat flow is 81 mW m⁻² in the Proterozoic rocks of the central region and 39 mW m⁻² in the western shield. At the mantle level both regions have heat flows of 27 mW m⁻². Evidently within-continent heat flow variations at the Earth's surface are due entirely, or almost entirely, to regional differences in crustal radioactivity and/or erosion. At the crust-mantle boundary the heat flow contours are simple closed curves centred on the continents and showing no regional complexities.

Finally, Pollack and Chapman are able to demonstrate correlations between the heat flow fields and other geophysical parameters. For example, both total and mantle heat flows correlate positively with the Earth's gravitational potential. However, the mantle heat flow correlates the less positively, suggesting that the broad geographic variations in the gravity field may be due in part to thermally produced heterogeneities in the crust. On the other hand, the fact that the positive correlation remains when the crustal contribution is removed suggests that thermal heterogeneities extend well into the mantle.

By contrast, both the total and mantle heat flows correlate negatively (the latter the more so) with topography, although this is produced by the first-order topography of the Earth (the gross difference in levels between continental and oceanic crust) which is largely a petrological rather than a thermal effect. When the continental and oceanic levels are normalised to remove this petrologically produced contrast, the total and mantle heat flows are found to correlate positively with topography, emphasising, according to Pollack and Chapman, "the significant role that temperature plays in the morphology of both continents and oceans." □

review article

Economics of alternative energy sources

Martin Ryle*

An important part of the oil and natural gas at present consumed in the UK is used for the heating of buildings, a demand which shows large diurnal, day-to-day and annual fluctuations. The replacement of this energy by nuclear-generated electricity, as at present envisaged, would require the construction of some 250 GW of additional capacity by the end of the century, a programme which does not seem feasible. By incorporating relatively cheap, short term storage in the form of low-grade heat, the generating capacity required to fulfil peak demand could be reduced by more than 50%. As soon as such storage is provided, however, other sources of energy become viable and attractive alternatives, and the UK is well situated to make use of wind, wave, and tidal power. It seems likely that the value of North Sea oil/gas reserves as feedstock to the chemical industry will rise sufficiently to make an early reduction in their consumption as fuel of great economic importance.

It is generally accepted that the energy at present provided by oil and natural gas will be approaching exhaustion by the end of the century, and that the resulting deficit must be made good by the widespread adoption of nuclear power, a large expansion of the coal industry or the development of alternative 'renewable' sources. Each of these possibilities has disadvantages and limitations, and there are problems of development on a short enough time-scale. Because the value of oil and gas as feedstock to the petro-chemical industries (which at present consume about 20% of the total¹) will increase rapidly as the reserves are depleted, it is of the greatest importance to introduce replacements as early as possible; each year gained represents a 4-year extension of supplies of raw material.

Since all of the potentially most useful renewable sources of energy in the UK (solar energy to supply heat or photo-voltaic electricity, wind, wave or tidal power) provide an intermittent or variable supply, their economic viability has always been based on whether they can be justified as 'fuel savers', and it has been assumed that they can never contribute to the 'base-load' in the sense of reducing the total installed capacity of conventional power stations. It then follows that, in order to be cost-effective, the interest on the capital costs of an alternative power system, together with its running costs, must be less than the fuel and running costs of a conventional system, without regard to the capital cost of the latter. Account must, of course, be taken of future inflation, interest rates, and relative costs of fuel in relation to the inflation rate, and the results of such analyses are often unreliable because of uncertainties about these factors, rather than in estimates of the engineering costs.

If the demand for power were constant, this treatment of alternative sources simply as fuel-savers would be a reasonable way of determining the viability of any particular system, but in practice this is far from being the case; there are very large variations in the demand for energy (diurnally, over the periods of 5-10 days typical of UK weather variations, and annually). At present, a com-

paratively small proportion (~ 15%) of the total useful energy is provided by electricity, and the variations in demand for it can normally be covered by the use of pumped hydro-electric stations, gas-turbine generators with a short run-up time, and by arrangements for selling off-peak electricity for water-heating and storage heaters. The fluctuating loads associated with space-heating of buildings and other consumers of oil and natural gas involve peak loads some 3 times the mean energy; at present short-term oil-storage can easily be supplied locally, with longer-term fluctuations covered by depôts or by varying the rate of abstraction through the year. The problem of accommodating the fluctuating loads when these latter energy sources are replaced by electricity does not seem to have been adequately discussed but would, in fact, be acute. I shall seek to demonstrate that a solution of this problem dramatically alters the balance in favour of 'renewable' sources of energy.

In the following sections an estimate is made of the distribution of oil and gas supplies amongst different users; the consequent diurnal, weather-system and annual variations of this additional electricity demand are then discussed in relation to the problems of generation and storage.

The figures are derived from UK Energy Statistics, 1973-75 (ref. 1) two NEDO reports on energy^{2,3}, the conference on 'Energy in the 1980s' organised by the Royal Society⁴, the Building Research Establishment Report on energy consumption in buildings⁵ and other sources. All energy values are expressed in terms of the electrical energy needed to replace them, so that they take account of the efficiency for the consumer of oil- or gas-burning heaters⁶; efficiencies of generation are taken into account in the establishment of the costs of different energy sources.

It is likely that for economic and other reasons the energy consumption in the UK will not increase in the manner assumed in earlier analyses²⁻⁴; better thermal insulation and the economic pressures towards lower temperatures in housing and other buildings, the production of longer-life goods, and better utilisation of industrial waste heat will all tend to maintain the recent trend towards lower energy

*Cavendish Laboratory, Madingley Road, Cambridge, UK.

consumption. For this reason it is not unreasonable to adopt the 1972-73 values for the energy consumption, the latest for which a detailed analysis is available³; the relative costs of different generating systems to replace the 1972-73 oil and gas consumption will in any case not be seriously affected even if the total varies from that of 1972-73. Greater uncertainties are caused by the rate at which coal production could (or should) be expanded, the development of more efficient methods of combustion⁶, and the relative costs of manufacturing gas, liquid fuels or other synthetic materials from coal instead of natural oil or gas, especially in relation to fuels for transport.

Although energy data for 1972-73 are used, the capital and operating costs are given in 1975 US \$ prices because much of the most useful data has been presented in this form; an annual inflation rate of 10% has been assumed for 1974-76.

Time distribution of additional requirements

It is assumed that the present (1972-73) UK electricity production (0.77×10^9 GJ p.a.) will continue to supply the present electricity demand, with the exception of the annual contribution (0.24×10^9 GJ) now provided by oil-powered gas turbines. Since the latter are used for peak load boosting, particularly in cold weather, it is assumed that their replacement will require an additional 0.024×10^9 GJ during the summer quarter, 0.06×10^9 GJ during each of the spring and autumn quarters and 0.096×10^9 GJ during the winter quarter; it is assumed that 2/3 of the latter will be needed during the cold spells of the 5-10-day weather pattern.

By taking the present distribution of oil and natural gas between each class of consumer⁷ we can derive the equivalent electrical energy demand and its variation with time of day, with outside temperature, an annually. The conversion efficiency of oil and gas heaters is taken as 60% (ref. 5) and that of electrical heating as 100%, although in some applications, such as water-heating for which off-peak use can help to even out the day-to-night demand, storage is necessary and an efficiency of 95% has been assumed.

The annual variation of the demand for space-heating in domestic and other buildings has been assumed, for simplicity, to be distributed uniformly throughout each quarter in the ratios 50%, 25%, 0% and 25%; this probably gives a rather low figure for the mid-winter requirements.

With present standards of building insulation, night/day switching is essential if a large increase in total demand is to be avoided, and a 50% cycle is assumed. Since the heat loss from a building is roughly proportional to the difference between internal and external temperatures (though it also depends on wind and other factors), there are large fluctuations with the timescale typical of UK weather patterns (5-10 days). A range of winter temperatures of -3 to $+11$ °C is assumed, with average 'whole-house' inside temperatures for the bulk of existing houses of 15.5 °C (60 °F). The hot-water demand is assumed not to vary significantly either annually or with weather conditions, and since 24-h storage is relatively simple it is assumed that two-thirds of the total demand could be restricted to off-peak times.

In the case of Industry it is assumed that, of the total equivalent electrical demand of 0.92×10^9 GJ p.a. at present supplied by oil and gas, there is a constant annual load of 0.72×10^9 GJ, of which 70% is consumed during the day, with an annually varying component of 0.2×10^9 GJ associated with space heating.

Some 95% of the transport energy is associated with road traffic, 67% of which is passenger traffic^{2,5}. Taking a weighted mean conversion efficiency between petrol (14%) and diesel (21%)² and a likely overall efficiency of 60%

for rechargeable batteries, hydrogen fuel cells or other possible storage methods, the equivalent electrical load is computed, with a constant annual rate, but on the assumption that 75% could be restricted to off-peak times in order to assist in reducing the day-to-night fluctuations.

The results are given in Table 1; the magnitude of the total energy demand, 2.1×10^9 GJ, should be compared with the present entire electrical output of 0.77×10^9 GJ, while it is evident that the fluctuations of demand require an extremely large additional installed capacity.

It has been suggested that a major increase in coal production might allow an increase of up to 50% by the end of the century. There are many alternative ways in which this increase might be distributed, but it is clear that part must be used to replace the present oil and natural-gas feedstock to the chemical industry. Assuming that this could be achieved with an efficiency of 90% of that of conversion from oil/gas, this would leave¹ an annual surplus of 0.36×10^9 GJ of equivalent electrical energy at 60% efficiency. This might be distributed (1) as at present, (2) to increase the electricity-generating capacity, (3) to supply direct heat to industry, (4) to increase gas production, (5) to produce synthetic liquid fuels for transport, particularly aviation.

Of these, (5) may be particularly important, and for the present it will be assumed that half the final energy is allocated to this with continuous production, and half to the manufacture of gas. Assuming an 80% conversion efficiency for gas^{4,5} and a similar figure for oil, the total equivalent electrical energy for each is 0.092×10^9 GJ. Since the gas contribution may be reserved, for example for on-peak domestic use, it could reduce the short-term fluctuations in the remaining demand curve, but could only reduce the annual fluctuations if gas stores (such as exhausted North Sea oil wells) or coal reserves and increased conversion plant capacity are provided; any resultant reduction in the annual fluctuations would only be possible, however, if a proportion of houses were equipped with both electrical and gas heating systems. It will therefore be assumed that long term storage is unlikely to be economic, but that a useful reduction in the peak winter loads can be achieved. The effects on the total

Table 1 Demand fluctuations (GW) and annual energy requirements

	Annual energy requirements (10^9 GJ)	Winter				Summer	
		-3°C		$+11^{\circ}\text{C}$		Day	Night
		Day	Night	Day	Night	Day	Night
Domestic:							
Space heating	0.241	49	—	12	—	—	—

Public buildings and so on:							
Space heating	0.233	48	—	12	—	—	—
Hot water	0.038	—	2	—	2	—	2
Industry:							
Plant	0.72	32	14	32	14	32	14
Space heating	0.20	41	—	10	—	—	—
Transport	0.34	5.5	16.5	5.5	16.5	5.5	16.5
Present gas-turbine generators	0.24	36	—	7.5	—	8.7	—
Total:	2.10	213	35.8	80.7	35.8	47.9	35.8
~ 150-h Storage			91			42	
Annual mean					66.5		
Assuming 50% increase in coal production	1.91	187	31	79	31	47	31
~ 150-h Storage			82			39	
Annual mean					60.5		

The intermediate values for the spring and autumn quarters are not tabulated, but are shown in Fig. 1.

residual energy demands are shown at the bottom of Table 1. It can be seen that, while a 50% increase in coal production would make a valuable reduction in the total additional electrical energy needed (besides supplying the chemical industry), large fluctuations on all timescales still remain.

These final figures will be used in the subsequent discussion, and are shown diagrammatically in Fig. 1; it is clear that a very large installed generating capacity would be needed to meet winter peak demands—more than 3 times that needed to supply the mean energy. It is, however, evident that the inclusion of storage can make a dramatic decrease in the installed capacity needed; the provision of ~ 150 -h storage capacity would smooth out both the 24-h fluctuations and those associated with the fluctuations of outside temperature, and permit a 55% reduction in generating capacity.

Central storage systems, whether in the form of pumped hydroelectric installations (for which there are limited further economic or environmentally-acceptable sites⁴), new types of battery, compressed air, hydrogen production or flywheels, all entail a threefold conversion of the energy and are therefore of poor overall efficiency. The major cause of the fluctuations is, however, associated with the provision of low-grade space heating for domestic and other buildings, so the natural solution, both cheap and efficient, is the storage of energy as heat at the point of consumption. The extensive use of heat-pumps could further reduce the peak demand when used in conjunction with such storage, although the efficiency is lowest in cold weather, just when the demand is greatest. The storage of heat over still longer periods has been discussed, but does not seem to be economically feasible^{5,8}.

As soon as storage on the ~ 150 -h time-scale corresponding to that of weather patterns is introduced, however, the main, objection to alternative, 'renewable', sources (that is the variability of output) disappears and it becomes important to examine both the annual variations in the output from such sources, and their capital and running costs relative to those of a nuclear system. Although solar energy has an availability even less appropriate than the constant output of a conventional power station, the outputs of wind- and wave-power systems have maxima during the winter months, in line with the variations of demand.

An attempt is made here to establish the capital and operating costs of both nuclear and alternative systems

Fig. 1 Diagrammatic representation of the fluctuations in demand of the energy at present supplied by oil and natural gas; the timescale of the 24-h and 5–10-day variations has been expanded for clarity. The heavy line indicates the smoothing produced by 150-h storage.

required to supply the demand curve of Fig. 1. Fairly accurate estimates are already available for the costs of solar heating and wind-turbine generators, because both have been investigated and used in other countries for a number of years. Wave-power, tidal and other hydroelectric schemes, and other applications for solar energy will require much detailed study before reliable figures for the energy potential and the capital and running costs become available.

It is assumed that nuclear and wind-turbine generators, and solar heating panels, can all be built with useful lives of 20 years.

A nuclear system

It is difficult to establish the cost of a nuclear power system. A 1975 price for SGHWR power stations based on projections from 1973 figures has recently been given⁹ as \$1,050 per kW of installed capacity, in close agreement with a more reliable contract price (July 1976) of $\$3.2 \times 10^9$ for a 2.4 GW station for New York State¹⁰; the latter figure corresponds to a 1975 price of \$1,130 per kW. This figure does not include the capital costs of the associated fuel re-processing plant, nor of the waste-disposal facilities; details of the latter do not seem yet to have been decided¹¹. The demolition cost of a fossil-fuel station at the end of its useful life is small compared with the capital cost of a replacement, but this may not be true for the demolition of a reactor. It seems unlikely that a value to include the above points will be less than \$1,250 per kW of installed capacity, and this figure will be adopted.

The reliability of nuclear power stations has been discussed by Sorensen¹² on the basis of 1974 international data¹³ and a 1975 survey of US commercial nuclear stations has been made by the Council on Economic Priorities¹⁴. The results represent 'capacity factors' (that is the energy actually generated compared with the maximum possible) of 55% and 60% respectively; the results are worse for the larger stations. While some of the lost capacity was due to routine maintenance, some of which could be restricted to the summer months, it seems unlikely that winter capacity factors $> 70\%$ will be achieved, and this figure will be used.

The true running costs of a nuclear power system cannot be assessed until a full analysis has been made of the problems of transporting fuel, the insurance charges which might have to be covered and the cost, both in manpower and energy, of providing protection for the indefinite future, of the waste-disposal sites.

The cost of energy from UK coal, oil, nuclear and hydro power stations during 1974–75 (ref. 1), (increased by 10% to allow for inflation to mid-1975), was \$3.92, \$6.6, \$1.19 and \$0.30 per GJ respectively, and this is assumed to reflect their total running and fuel costs. In the case of fossil fuel stations, most of it is attributable to fuel costs, but in the case of nuclear stations the subdivision cannot be made until the type of reactor, the corresponding fuel processing costs, and the future effective costs of lower grade ores etc. are known. For the present it will be assumed that the nuclear fuel costs should be divided equally between fuel and running costs. Since some account must be taken of the additional costs mentioned above, a total of \$1.25 per GJ will be assumed, half being related to the installed capacity and half to the energy produced.

Various estimates have been made¹⁵ for the cost and efficiency of energy storage systems, including batteries, compressed air, hydrogen production and flywheels, and range from \$18 to \$45 per kWh; all these systems are, however, intended for reconversion to electrical power. While some central storage may be necessary, the variations in demand are dominated by the low-grade ($< 100^\circ\text{C}$) energy needed for heating buildings, for which cheaper, local, storage may be used. Such a system has recently been installed in the UK at a 1975 price of \$1.5 per kWh (J. Keable, personal communication).

Table 2 The capital and running costs (in 1975 \$) of producing 1 GJ annually with the time variations shown in Fig. 1; for all non-nuclear systems costs include storage

	Capital cost	Annual running cost	Total for 20 years
Nuclear (a) no storage	174	3.6	246
(b) 150-h storage	90	2.1	132
Solar panels	85	0.5	95
Wind	49	0.8	65
Wave	[125]	[3]	[185]

It is now possible to determine the installed capacity, and hence the capital required to provide an annual energy of 1 GJ with the time variations shown in Fig. 1, (1) without storage, (2) with storage at \$2.0 per kWh (allowing for some central storage) (Table 2). The corresponding figures for the running cost per GJ and the total of capital and running costs over the 20-year life of the station are also given; no account has been taken of inflation, since the figures are intended merely to give some idea of the relative importance of capital and operating costs for the different systems.

Alternative energy sources

The first alternative energy source I shall consider is solar energy. The mean annual variation of incident solar radiation (at Kew) is shown in Fig. 2a for (1) a horizontal collector and (2) a vertical collector facing south⁷. About half of the collected energy is due to direct sunlight and half to diffuse light. When used for providing low-temperature heat, simple collectors may be used with typical efficiencies of 40–50% (ref. 5).

This curve is not well matched to the annual variations of Fig. 1, although solar panels are already marginally cost-effective as fuel-savers for pre-heating the supply to hot-water systems⁵. The Building Research Establishment has concluded that about half of the existing houses could each be fitted with 6 m² of panel to provide 7 GJ per annum at a capital cost of ~\$330 or \$47 per GJ; the total annual energy for the number of houses which could be so equipped was estimated as 0.07×10^9 GJ (ref. 5). For new houses, where the cost of part of the roof can be subtracted, or where the design of the house as a whole can include provision for using and storing solar energy, the cost would be appreciably less; more economical designs, both of the panel and, the auxiliary components of the system, are likely to reduce the cost even for existing buildings to ~\$25 for a total annual energy supply of 1 GJ.

In order to contribute the winter values corresponding to 1 GJ having the annual distribution of Fig. 1, the area of panel would have to be increased by a factor of 4.2 (horizontal) or 2.6 (vertical south-facing). Since not all of the houses could be fitted with the latter, an intermediate value of 3 will be assumed. The capital cost of providing 1 GJ having the time-distribution of Fig. 1, must therefore be taken as \$75, although the total annual energy provided is now 0.21×10^9 GJ; the excess energy is not necessarily wasted when 150-h storage is taken into account, since at all times of the year averaging of sunny/cloudy conditions increases the useful energy abstracted, except in summer when the output may be larger than can be used for hot water heating.

Similar installations on public and industrial buildings requiring water heating could increase the total energy to ~ 0.3×10^9 GJ annually, and contribute winter powers equivalent to 0.1×10^9 GJ in the form of Fig. 1. The capital cost per GJ of the latter, including storage, is given in Table 2, together with the small running costs for which a token figure of \$0.5 per GJ is assumed. Other possible developments of solar power are discussed later.

The second possibility is wind power. The annual variation

of the energy available from the wind has been discussed in a paper by Golding and Stodhart¹⁶. The most useful range of wind-speeds (containing some 80% of the total energy), is typically 5–15 m s⁻¹ in the UK and data collected at 7 meteorological stations over periods up to 10 years have been used to derive the useful energy in each month¹⁶. For the five sites situated around the coastal belt and most suitable for wind power, the average annual variation (expressed as a percentage of the mean) is shown in Fig. 2b. The data from two Midland areas with low wind speeds, and one in the Western Isles with very high wind speeds, have been excluded, although in fact the curves are similar.

A comparison of Fig. 2b and Fig. 1 shows that the annual variation of wind power is well matched to that of the demand and, since the variations of wind speed occur with the same 5–10-day periods typical of UK weather, the use of a storage system similar to that described will equally remove these, provided that a more flexible method of load-switching is introduced. Detailed records are available from four of the five sites¹⁶, and have shown that the longest periods of calm (< 4.5 m s⁻¹) vary from 18 to 209 h (the latter over a time span of 10 years); the longest period in the winter quarter with 118 h. Since these calm spells are frequently restricted geographically¹⁷, the actual variations in power available from a distributed wind-power system connected to the grid would be further reduced.

A detailed analysis of the power available annually from

Fig. 2 a, The annual variation of the energy available from solar radiation. ○, Horizontal collector; ×, vertical, south-facing collector. **b**, The annual variation of the energy available from wind power, expressed as a fraction of the mean energy.

a small domestic wind-turbine of given swept area has been made by Rayment¹⁸. Using his figures for the wind at a height of 10 m (corrected for the wind at the height of 35 m appropriate to the large turbines, 55–60 m in diameter, discussed below), the energy available is such as to provide an annual electrical output of $\sim 2.3 \text{ GJ m}^{-2}$ of swept area in the east and southern coastal regions, and 3.2 GJ m^{-2} in the western coastal regions, with values $> 5 \text{ GJ m}^{-2}$ in N.W. Scotland and N. Ireland.

The vertical mixing of the air allows one to site wind-turbines so that their swept area corresponds to between 1.5×10^{-2} and 1.5×10^{-3} of the ground area (refs 19, 20, 21, 22); taking a value of 4×10^{-3} and a mean density of 2.8 GJ m^{-2} , the annual electrical energy would be $\sim 11,200 \text{ GJ km}^{-2}$. These coastal areas have a total area of about $1.5 \times 10^5 \text{ km}^2$.

The whole area could not, of course, be used, though the impact of such wind-turbines, e.g. on agriculture, is minimal. (If 50–60 m diameter turbines ($\sim 1 \text{ MW}$) were used, the structure would be comparable with a 275-kV grid-pylon and their separation would be $\sim 1 \text{ km}$. Since local connections would be at medium-voltage, their visual impact would, in fact, be little different from a nuclear system in which most of the power stations would have to be sited on the coast; the number of (275-kV) pylons within the coastal belt for the latter system would be about two-thirds that for the wind system).

In some areas, as with grid lines, there would be strong environmental objections although, unlike those which apply to a nuclear system, they would be limited to their visual impact. For the present it will be assumed that only one-third of the coastal area considered could be used, with an annual output of $0.56 \times 10^9 \text{ GJ}$. It has been suggested¹⁹ that wind-turbines could also be built in shallow and accessible off-shore areas, such as the Wash and Thames Estuary; while the capital costs of building the turbine and of transmission ashore are greater than those for a land installation, the greater wind speeds would provide an annual energy ~ 5 to 10 GJ m^{-2} instead of the value of 2.8 GJ m^{-2} assumed for the coastal area; the capital costs per GJ may therefore be no greater than for the land installations considered. It seems probable that a further $0.4 \times 10^9 \text{ GJ}$ could readily be provided in this way. The total of $0.96 \times 10^9 \text{ GJ}$ having the annual variation of Fig. 2b would provide an average power of $\sim 43 \text{ GW}$ during the winter quarter, and $\sim 20 \text{ GW}$ during the summer quarter.

Whereas an increase of scale introduces significant economies in conventional power stations, it is not yet clear that this is the case for wind-turbines much greater than 1 MW . The following analysis is therefore based on turbines up to 1 MW for which considerable information on design and cost is now available; for example several installations with capacities up to 200 kW were built in Denmark, and 800-kW and 1-MW turbines were built in France, and were used to provide power for their respective grid-systems during 1955–65^{15,23,24}. The Danish report²³ concluded that by 1975 wind-turbines of this size were cost effective relative to oil-fired power stations even as fuel-savers. The capital cost of their 1957 experimental 200-kW design installed at Gedser, when converted to 1975 prices, was $\$280 \text{ per m}^2$ of swept area for production on a limited scale. A more modern design would have $\sim 40\%$ greater efficiency²³, so this figure, with UK wind speeds, would correspond to about $\$700 \text{ per kW}$ of installed capacity. It is, moreover, likely that a modern wind turbine would be cheaper, largely owing to the development of reliable solid-state devices, which allow the use of a more efficient turbine blade running at fixed pitch (thus removing one of the most serious stress problems) and driving a variable-speed alternator by way of a simple fixed-ratio gearbox, thus avoiding both the complexity of variable-ratio gearboxes and the need for synchronisation with the grid. The output of

such an alternator can easily be varied to present the optimum torque-speed relationship, and would probably be converted to fixed voltage d.c. and transmitted to a sub-station collecting the output from a number of installations for inversion and supply to the grid. A cost significantly below the figure of $\$700 \text{ per kW}$ is therefore to be expected.

The analysis of the Mitre Corporation¹⁵ gives a figure of $\sim \$500 \text{ per kW}$ for a 100-kW installation and $\$300 \text{ per kW}$ for a 1-MW installation—again for a rated wind speed (12 m s^{-1}) appropriate for the UK. Recent design studies²⁵ for 1.5-MW turbines, for lower rated speeds (10.7 m s^{-1}) but rather higher mean wind speeds (8 m s^{-1}) by the General Electric and Kaman Companies in the USA gave costs of $\$449$ and $\$481 \text{ per kW}$ of installed capacity; these use a synchronous alternator which, as discussed above, is not likely to be the most economical system, except for use over a narrow range of operating wind speed. A recent design study by Wesco (G. W-W. Pontin, personal communication) of Redhill for a 46-m diameter turbine and for the assumed UK wind pattern gives a figure of $\$275 \text{ per kW}$.

All the above systems are based on conventional horizontal-axis turbines; it is possible that more economical designs using a vertical axis will be developed^{19,26}.

If the local transmission and substation are included, it is therefore reasonable to adopt a figure of $\sim \$500 \text{ per kW}$ of installed capacity. The remaining transmission costs, as already discussed, are not likely to exceed those of a nuclear system.

From statistics of the wind and an assumption of 90% mechanical serviceability, it is now possible to compute the installed capacity, and hence capital cost, of a wind system needed to provide each GJ with the annual variation of Fig. 1. This figure when added to the storage cost, is included in Table 2.

The Danish report concluded that the running cost of a wind system would be $\$0.93 \text{ per GJ}$, although this figure is probably an overestimate in the light of the improvements and simplification of design discussed above; the corresponding figure from the Wesco data is $\$0.4 \text{ per GJ}$. A value of $\$0.8$ will be used.

The third possibility is wave power. A useful survey of the energy available from wave power has been made by Glendenning and Count²⁷ who give, for the West coast of the British Isles, average annual powers of $50\text{--}100 \text{ kW per m}$ of collector. The medium-term fluctuations in power are very similar to those for overland wind, with a marked variability on a timescale of 5–10 days, while the average available power in winter is again about $2\frac{1}{2}$ times that in summer. Since much of the energy originates in waves generated at distances $> 1,000 \text{ km}$, the 5–10-day fluctuations will not be correlated with those of overland winds, so that a combination of wave and wind power will show smaller fluctuations than either alone.

The cost has been estimated as $\$600\text{--}\$1,200 \text{ per kW}$ of installed capacity²⁷ but this estimate must be regarded as provisional; work supported by the Department of Energy at the University of Edinburgh, the National Engineering Laboratory, and Wavpower Ltd should lead to a more accurate figure after study of the practical problems of mooring such devices in deep water, their survival during storms and the restrictions and dangers to shipping; since some 300 km of collector would be necessary to equal the annual power output of the wind system considered, this latter point is clearly important.

The problems of bringing the power ashore are also much more severe than those involved in either nuclear or wind systems, whether an electrical cable, piped-hydrogen or any other method is used; for the present a capital cost of $\$1,500 \text{ per kW}$ will be assumed, with a serviceability of 80%. The running costs and maintenance of the collector structure will also involve a considerably greater cost per GJ than for a wind system.

Implications for bridging the energy gap

The large fluctuations in the energy demand at present supplied by oil and gas require a generating capacity, for an electrical alternative, some 3 times that needed to supply the mean energy. It does not seem feasible to build the ~266 GW of nuclear generating capacity required before the end of the century. If storage, of ~150 h duration, is included into the system to smooth out the diurnal and weather fluctuations, the installed capacity could be reduced to ~117 GW; the cost of the storage, most of which would be at the point of consumption, would be much smaller than that of the generating capacity saved.

As soon as such storage is introduced, however, a number of the alternative sources of energy can be compared, on an equal basis, with a nuclear system. Table 2 shows that wind energy is the cheapest of all the 'renewable' sources developed so far, and that a system based largely on wind turbines is very much cheaper, both in capital and running costs than a nuclear system; since the figures are based on experience with actual machines comparable in size with those envisaged, any uncertainties in the costs are unlikely to alter this conclusion.

The energy curve produced by the example wind system described is given in Fig. 3, which shows that it would supply half of the demand throughout the year.

The installation of solar panels also provides cheap energy although its poor fit to the annual demand curve increases the effective cost significantly above that of a wind system. It would be useful mainly for hot-water supply, and the installation discussed would contribute the energy curve also shown in Fig. 3. It can be seen that these two sources would together provide a major part of the total demand. The remainder might be obtained either by extending the wind system or by wave power or new types of hydro-electric system²⁸. For the particular case of fuels for transport, plant photosynthesis may become cost-effective. (For example, sugar-beet converts 4.3% of solar energy while methane production from fermentation of sewage, straw and crops such as *Spartina*, which grows on salt-marshes, would not require the use of land suitable for food production⁷).

The actual introduction of the wind system (and solar panels) could be straightforward and quick. An alternative off-peak load-switching system would be needed in place of the rigid time-switches at present in use. The replacement

Fig. 3 The total energy (in relation to the smoothed demand of Fig. 1) provided (a) by the wind system described (shaded), (b) by the installation of solar panels as described, and (c) by both combined.

Fig. 4 An experimental 3-m (2-kW) wind-turbine at Cambridge used for the design of efficient blade profiles and methods of load matching and for the investigation of the non-steady loads due to gusts.

of these clocks with a (probably cheaper) detector of a high-frequency carrier transmitted via the mains from the substation (as has been used for street lighting and other switching operations), would allow the load to be adjusted to meet the energy available whatever its time or geographical variations; such a system would also have the advantage of allowing better use of existing generating capacity (for example, weekend surplus, avoidance of high peaks at the start of the off-peak period when thermostat switches are all closed).

As with all alternative systems a single prototype unit of small cost coupled with site surveys allows a reliable estimate of the cost and performance of a complete system, in marked contrast to the expense of building a prototype reactor. In the development both of a prototype wind-turbine, and in subsequent production, about 60% of the cost is accounted for by the tower, gearbox and alternator¹⁵, all of which are virtually 'off-the-shelf' items. The blade design seems to be a problem well within the capabilities of the British aviation industry on a timescale of 6–12 months and a production prototype could be operating within 18 months with the expenditure of perhaps \$1–2 million (the first full-scale Hovercraft flew 8 months after design started).

The subsequent production could build up over a 5-year period to 2,000 units a year (representing, in both cost and tonnage of steel, 10–15% of that of the UK motor industry) and divided approximately equally between the structural steel, the electrical and the aircraft industries. By 1985 wind energy could be providing $>10^7$ GJ annually and the energy consumed in the manufacture of each unit² would be repaid by it in 6–12 months.

In contrast, unless large scale production of an existing reactor design were adopted, the introduction of a nuclear system is inevitably slow. In the case of a new design, such as the proposed FBR (for which there may in any case, be a limitation of ~3% per year in the increase of the system output due to limitations of fuel supply^{11,29}) it would be necessary to build and test, on a timescale of 8–10 years, a prototype before construction of further stations can proceed.

If such a prototype (say, 2–3 GW) were in operation by 1986–87, and a period of perhaps 3–5 years were necessary to repay the energy involved in its construction, fuel extraction and processing and so on, it would only begin to supply useful energy (as Fig. 1) by about 1991, at an annual rate of $\sim 2 \times 10^7$ GJ; the wind system discussed, with a production

of 2,000 units p.a. would, by then, be producing an annual output of about 2×10^8 GJ.

Not only does wind energy seem to be the cheapest way of reducing the energy gap, it is the only way of making a significant contribution within the next 12–15 years, and so allow the preservation of some of the North Sea oil for the future.

Although the discussion has been limited to the specific problem of UK energy supplies, the conclusion may have even greater application in other parts of the world, most of which have either adequate wind or solar resources to support the needs of a lower density of population; the straightforward technology requires only simple maintenance and none of the security problems of nuclear stations. The possibilities of very large export markets should add further incentive to develop the first production version of a 1 MW wind-turbine.

A chaotic cosmology

John D. Barrow

Department of Astrophysics, Oxford University, Oxford, UK

An anisotropic, inhomogeneous cosmological model is proposed in which the inhomogeneity is generated by shear fluctuations. This is a sufficient condition for dissipative heating by collisional neutrinos to explain the present large heat content of the universe, $S_{\text{b.o.}} \sim 10^8$, together with its isotropy and comparative homogeneity on large scales when the photons were last scattered. The model does not require the chaotic motions to be arbitrarily truncated on large scales and isotropises early enough with high entropy to ensure the synthesis of light elements with the observed abundances. A population of black holes which arises in a natural way can also provide the necessary ingredients for a theory of galaxy formation and morphology. The 10^{15} -g black holes, predicted by some authors, are not necessarily expected to be a feature of chaotic cosmologies.

MISNER¹ first pointed out a fundamental problem which measurements of the microwave background isotropy had created². He drew the attention of cosmologists from seeking an explanation for the presence of local enhancements over the background density on galactic scales in terms of random fluctuations to asking why the background universe should display a high degree of isotropy and homogeneity at all. This approach to cosmology was termed 'chaotic cosmology' and in its most general form seeks to show that the observed structure of the universe is demanded rather than merely permitted by the physical processes acting within it. It was thus hoped that

general relativity would predict that the universe is unique in theory as well as in practice, irrespective of its initial state.

Early attempts by Misner to resolve, within the framework of classical relativity, the problems of the contingency of isotropy and the apparent non-intersection of past light cones, together with the fundamental difficulties they encountered at a classical level are well known (see ref. 3). It is still hoped that a complete resolution of the problem will come by appealing to quantum phenomena in the first 10^{-43} s of the Universe's life, but as this route is at present still beset by many conceptual and technical problems⁴ it is interesting to investigate what may be achieved by known classical effects and it is at this level that we address the problem.

The most important unexplained properties of the universe for which cosmologists seek an explanation are probably: (1) The large scale homogeneity and isotropy as indicated directly by the absence of structure in the intensity of the microwave radiation on large angular scales $(\Delta T)/T \leq 3 \times 10^{-3}$ (ref. 2), and indirectly by the observed cosmic mass fractions of helium ~ 0.3 and deuterium $\sim 2 \times 10^{-5}$ predicted by the open homogeneous, isotropic Robertson-Walker (RW) cosmological model⁵. (2) The large heat content of the background radiation, dimensionlessly characterised by the number of black-body photons per baryon, $S_0 \equiv (4a/3k) (T_0^3/n_0) \sim 10^8 \gg 1$ (where a is the radiation constant, k the Boltzmann constant, $T_0 = 2.7$ K, the present radiation temperature and $n_0 \sim 10^{-6} \text{ cm}^{-3}$ the present baryon number density). This is unusually large for a dimensionless physical quantity, but far smaller than the other large cosmic numbers $\sim 10^{40}$ (ref. 6).

The existence of such a uniform physical system in this high entropy state is highly suggestive of there having been a con-

siderable amount of dissipation in the past, although the finite value of the entropy indicates that there could not have existed an arbitrarily chaotic initial state³². (3) The origin of protogalactic inhomogeneities with amplitudes sufficiently large to generate distinct structures on scales $\sim 10^{11}$ – $10^{15} M_{\odot}$ by the present era, yet sufficiently small to avoid a proliferation of compact objects in the same mass range. (4) The absence of developed structure on scales larger than $\sim 10^{15} M_{\odot}$ and the apparent absence of a preferred scale of galaxy clustering over the range 10^{12} – $10^{15} M_{\odot}$ (ref. 7). In conjunction with (3) this presents the problem of explaining the observed spectrum of inhomogeneities at recombination.

The aim of this paper is to outline a chaotic cosmological model in which the above features of the universe might be explained by a hypothesis concerning the type of non-uniformity present at the singularity. There have been many attempts to explain the above problems (1)–(4) in isolation; for example the work of Misner and Matzner⁸ on (1); Rees⁹, Zeldovich¹⁰ and Liang¹¹ on (2). Many workers have discussed aspects (3) and (4) (ref. 12).

The model described here owes much to the chaotic cosmology conceived by Rees⁹, combining other features to improve and extend it.

The Rees cosmology

In brief, the Rees cosmology consists initially of an approximately isotropic distribution of baryons with large amplitude inhomogeneities, $\delta\rho/\rho \sim 1$, on each scale as it enters the horizon. The radiation content of the universe is then generated exothermically by the nonlinear dissipation of the acoustic waves as their scale is encompassed by the Jeans length. For a state of maximal chaos the energy budget is given by $aT^4 \sim \rho_b c^2$, which gives an entropy production–redshift relation, $S = 10^{13} (1+Z)^{-1}$. The shocking of acoustic fluctuations can thus generate the radiation content of the universe by a redshift, $1+Z_f \sim 10^5$. Rees points out that the expected small scale matter clumping on scales less than the photon diffusion length enhances the free–free production rate and enables the created radiation to be adequately thermalised at this redshift. Interestingly, the clumping of matter on scales larger than the photon diffusion length would, in complete contrast, make thermalisation much more difficult than in a smooth model of the same average matter density. This effect could provide an interesting constraint on the existence of lagging cores in the early Universe as envisaged by Harrison¹³.

To prevent the production of more entropy than is observed in the microwave background one must truncate the chaos on the horizon scale corresponding to $1+Z_f \sim 10^5$ encompassing $\sim 10^{17} M_{\odot}$, which is close to the mass of the largest observed structures in the universe. This scheme also explains the approximate coincidence of the epoch of recombination and the onset of matter domination, $Z_{eq} = 10\Omega Z_{rec}$ where Ω is the ratio of the present baryon density to the closure matter density.

Attractive as this conception is, it does however possess a number of undesirable features.

(1) The presence of inhomogeneities having $\delta\rho/\rho \sim 1$ on horizon sized scales with their associated lightlike peculiar velocities is not consistent with the assumption of global isotropy. As a consequence the expansion timescale will accordingly be shortened to correspond with a locally anisotropic (say, Kasner-like) structure for $Z \geq 10^5$. Some of the implications of this situation are mentioned below.

(2) The final entropy, $S_b \sim 10^8$, is principally generated by the dissipation of the largest chaotic mass scales. For shock dissipation the entropy production obeys $S = 3 \times 10^{13} T^{-1}$. This means that during the period $Z \sim 10^9$ – 10^{10} , conducive to light element synthesis, the specific entropy $\sim 10^4$ is too low to produce the observed deuterium abundance $\sim 10^{-5}$, under-producing it by a factor of $\sim 10^8$ and also producing a dis-

cordant helium fraction of 40% in excess of the observed 30%. If one also takes into account the accompanying effects of anisotropy the discord becomes even worse, three anomalous situations being possible according to the degree of anisotropy at the time of nucleosynthesis, $T \sim 10^9$ – 10^{10} K. First, a helium abundance of ~ 60 – 100% in a state of high anisotropy and thermal equilibrium. Second, indeterminate abundances of all light elements if the expansion time scale is less than the weak interaction time but greater than the slowest nuclear reaction time scale. And third, zero abundances of all light elements heavier than hydrogen when the expansion time is less than both weak and nuclear reaction times.

The latter two possibilities can arise in models in which matter motion at near light-like velocities leads to a Lorentz contraction of the expansion time scale in the rest frame of the moving matter^{14,33}.

(3) There is the necessity for an arbitrary cut-off to the chaotic motions on scales larger than $\sim 10^{17} M_{\odot}$. No physical mechanism is suggested which could bring about such a cut-off. The only possible mechanism would seem to be a photon ‘viscosity’ due to the long mean free paths of decoupling photons. The scattering of photons by non-relativistic electrons would give rise to a constant viscosity $\eta = m_e c \rho_e (kT \sigma_{Te})^{-1}$ apparently capable in theory of damping homogeneous shear of infinite wavelength. The recombination of the plasma takes place too rapidly for there to be a viscous period of any significance, however, and any extension of the viscous epoch due to the dissipative heating would seem to be prohibited by the Planckian form of the observed spectrum¹⁵.

(4) The degree of large scale anisotropy compatible with the required inhomogeneity at $Z \sim 10^5$ would almost certainly do violence to the observed constraints $(\Delta T)/T \leq 3 \times 10^{-3}$, on the microwave anisotropy at last scattering unless there occurred sufficient reheating of the cosmic plasma at late times to defer its last scattering until $Z \sim 10$. There are, however, strong limits to the amount of anisotropy energy which can be ‘buried’ in the microwave photons by dissipative processes at late times since distinctive spectral distortions can be expected to arise¹⁶. B. J. T. Jones has pointed out that these distortions cannot yet be predicted straightforwardly as the Kompaneets’s equation describing the evolution of the general photon spectrum is of a different character in a non-uniform environment¹⁶. One would not expect anisotropy to alleviate this distortion in the way suggested by Rees³¹ since the anisotropy must be damped out before the photons are thermalised.

Prolific black hole formation on all mass scales up to $\sim 10^{17} M_{\odot}$ might also be expected and would be in glaring contradiction to observation¹⁷.

(5) The results of Peebles¹⁸ and E. T. P. Liang (preprint, 1976) indicate that difficulties are encountered if one attempts to explain the observed structures on globular cluster and galactic scales as a residue of nonlinear damping. Shocking is highly efficient as an eradicator of large amplitude, short wavelength fluctuations, damping out the adiabatic fluctuations on relevant scales $\sim 5 \times 10^{11} \Omega^{-1} M_{\odot}$ completely and one must appeal to fragmentation of large $\geq 10^{14} M_{\odot}$ clumps or isothermal perturbations to describe the presence of galaxies. In fact the damping is probably much more efficient and even larger scales removed than those predicted by Liang since his calculation based upon a simple wave picture in which the self-interaction of single sound waves is adequately described but their mutual interaction is not. A more complete picture of ‘acoustic turbulence’ including these effects might give rise to more efficient dissipation over larger scales than the simple wave picture.

A new model

We describe here an initially anisotropic and inhomogeneous cosmology which generates the observed microwave radiation by the dissipation of chaotic motions but in which the chaos is

damped out on all scales at early times. In this way one enables light element synthesis to proceed as in the standard RW models and the radiation background to become isotropic with Planckian spectrum without having to invoke small scale clumping or re-ionization at late times.

We shall take the singularity structure to be defined by an anisotropic and inhomogeneous zero entropy state filled with pressureless dust. This is locally equivalent to a Kasner universe with large amplitude, $\delta\rho/\rho \sim 1$ matter perturbations on all scales when they enter the horizon. The work of Belinskii *et al.*¹⁹ indicates that such a representation is sufficiently general to constitute an open neighbourhood in the superspace of all cosmological solutions to the Einstein equations. It is also a self-consistent picture since the presence of global spatial inhomogeneity implies anisotropy in the expansion dynamics. We now hypothesise that the inhomogeneity be limited to that class which is generated by equilibrium shear fluctuations, the meaning of and reason for this restriction will be explained below.

The very early evolution of this model is envisaged as proceeding in similar manner to the Rees cosmology, entropy being generated by relativistic shock damping of the large amplitude acoustic waves, leading to a growth of entropy according to the relation $S = 3 \times 10^{13} T^{-1}$, as above. This process proceeds efficiently since the relatively soft equation of state guarantees that the local sound speed is much less than the peculiar velocities induced by the inhomogeneity. More rigorously, solution of the fluid dynamical equations for test motion in the anisotropic background shows that the velocity field satisfies

$$U_k = f[(x_k \pm ((ct^{1-p_k})/1 - p_k)]$$

where U_k is the fluid three velocity, f an arbitrary differentiable scalar function and p_k are the usual Kasner indices satisfying $-\frac{1}{3} \leq p_1 \leq 0 \leq p_2 \leq \frac{2}{3} \leq p_3 \leq 1$; flow singularities thus develop.

This process will continue to produce entropy until the temperature falls to $\sim 10^{11}$ K when the influence of weakly interacting particles^{8,20} becomes crucial to a discussion of the dynamics. It is at this temperature that the viscous action of decoupling electron and muon neutrinos can lead to the damping of the expansion anisotropy. We consider the equilibrium neutrino case, with the neutrino-electron scattering time shorter than the expansion time, $t_{\nu e} < t_{\text{exp}}$, in which the corresponding coefficient of viscosity is derived from the Feynmann Gell-Mann theory of weak interactions, $(20)^*$, with $\eta \sim \rho t_{\nu e} \sim T^{-1}$. (The existence of neutral currents make a negligible difference to the result.) We describe the anisotropy by the ratio of the anisotropy energy density, to that of the thermal energy, defining

$$A \equiv \rho_B/\rho_T = \sigma^2(NaT^4)^{-1}$$

where σ is the kinematic shear and N the weighting function for the particle species. It can be shown that the equilibrium neutrino assumption restricts the allowed anisotropy to $A \sim 10^6$. (This is demonstrated by comparing the ratio of the neutrino-electron collision time, $t_{\nu e} \sim 10^{59} T^{-5}$ to the expansion time $\sim (G\sigma^2)^{-1/2}$ at the dissipation epoch when $T \sim 5 \times 10^{10}$ K). By calculations analogous to those of Misner²⁵, it can be shown that in this case the viscous action of the neutrinos is always effective in reducing the anisotropy energy from its maximum allowed equilibrium value, $A \sim 10^6$, to $A < 1$ within an expansion time and the growth of entropy is $S/S_i \sim 10^5$, where S_i is the value of the specific entropy before the neutrino viscosity became effective. This is precisely the amplification factor necessary to augment the shock generated entropy, $S_i \sim 10^3$, to the required value, $S_0 \sim 10^8$ for the products of nucleosynthesis at $T \sim 10^9$ K to be in agreement with observation. (For a general temperature dependent viscosity $\eta \sim T^n$, we find

$$S/S_i \sim 5 \times 10^{6(1-n)/(2-n)} / T_i^{(n^2-1)/(2-n)}$$

where T_i is the adiabatic temperature at which viscous dissipation commences, so $\rho_{vi} = NaT_i$. These results can be obtained from those of Matzner³⁴.) Some vorticity will also be created in the shock fronts and by the viscous dissipation itself²¹ but this is created only on $\lambda < vt$ scales where photon viscosity will subsequently damp it out and it thus has questionable relevance to turbulent models of galaxy formation.

Now we also notice that since the inhomogeneity is generated by shear fluctuations it will also be damped out by the neutrino viscosity, even on scales larger than the horizon. No acausal process is implied here, for as the infinite wavelength homogeneous shear is damped so is its global fluctuation. More formally we know that a space which is locally isotropic everywhere must be spatially homogeneous and here it is the action of the constraint equations of elliptic character that force the space into a homogeneous state. Such an effect has been found in the case of small inhomogeneity by Liang²² but was not interpreted physically and it is in fact also apparent in the results of Stormer²³. The smoothing process can also be viewed in terms of the initial value problem. The evolution equations are hyperbolic but the initial conditions are set so that non-communicating domains share some common features. In particular, fluctuations on scales smaller than the horizon are everywhere damped and hence appear damped on scales greater than the horizon (M. A. H. MacCallum, personal communication).

Thus the viscous mechanism is also effective in removing the inhomogeneity on all scales by the time the temperature has fallen to $T \sim 10^9$ K and on large $\lambda > ct$ scales the universe is then effectively the standard Robertson-Walker model—the structure on smaller scales is discussed below. The model can then generate the observed helium and deuterium abundances in the usual way with the proviso that the entropy dependence of the latter is modified by the effects of its small scale fluctuation.

Finally, we turn to the problem of the possible origin of suitable protogalactic structures. Clearly we could make the *ad hoc* assumption that there exist growing curvature fluctuations with $\delta\rho \sim 10^{-6}\rho$ on all scales when they enter the horizon as required in the theories of Zeldovich *et al.*²⁶ and Gott and Rees²⁷, which would escape any viscous dissipation on scales greater than the horizon. Such a state of affairs is unconvincing, however, and a second possibility arising naturally in the model is more interesting.

Meszaros²⁴ has proposed a theory of galaxy formation based on the hypothesis that a fraction of the matter in the early Universe collapsed to form a population of low mass black holes, the subsequent fluctuation in their number density constituting a non-decaying isothermal density perturbation. The absence of electromagnetic coupling between the black holes and the background radiation field ensures that they behave as entropy perturbations experiencing no damping by radiative pressure. Their amplitudes on scales smaller than the horizon remain frozen until the radiation ceases to dominate the expansion dynamics, after which linear growth proceeds in the usual way. This scenario is shown to lead to a consistent theory of galaxy formation and morphology at later times. In Meszaros' work the origin, number density and mass of the black holes are all arbitrary parameters chosen as initial conditions to guarantee the right amplitudes at recombination. In the model described above, however, such a black hole population arises naturally during the viscous damping period while the model is undergoing isotropisation. The shocking of inhomogeneities when they enter the Jeans length will not be completely efficient and when the sound speed is c_s we would expect some inhomogeneities of amplitude δ to collapse into black holes with a probability $\sim \delta \exp(-\frac{1}{2}c_s^2\delta^{-2})$ (ref. 17), if their amplitudes are appreciable on scales intermediate between the Jeans and horizon masses. At first sight it might seem from the results of Carr that black holes will form prolifically on all scales below $\sim 1M_\odot$ leading to $\rho_{bh} \sim \rho_{\text{dust}}$ in this mass range and thus causing the Hawking evaporation¹⁷, at the present epoch of

those with $M \sim 10^{15}$ g to violate the limits on the observed γ -ray flux in the 100 MeV range which requires $\rho_{bh} (10^{15} \text{ g}) < 10^{-6} \rho_{dust}$. We claim, however, that black-hole collapse will only occur on horizon sized scales during the isotropisation and homogenisation process itself when $A \leq 1$. This will produce a population of small black holes with mass $\sim 1 - 10^4 M_\odot$ and their density must satisfy $\rho_{bh} \leq \rho_{dust}$. The reason for this restriction in the mass range is that the calculations of Carr model the inhomogeneity as a curvature fluctuation by joining different RW models together. The space-time is thus allowed global isotropy although here global anisotropy is required for self-consistency. Now, whereas in an isotropic universe the collapse time for the matter $\tau_c \sim \rho_\gamma^{-1}$ equals the expansion time τ_{ex} and collapse can readily occur, this will not be the case in an anisotropic background where the expansion rate is

$$\left(\frac{\rho_B}{\rho_\gamma} \right)^{\frac{1}{2}}$$

times faster.

Thus, as the collapse time remains $\sim \rho_\gamma^{-1}$, anisotropic dynamics guarantee $\tau_c \gg \tau_{ex}$ and there is insufficient time for the black holes to form. A more physical explanation is that the dominant anisotropy pressure determines the Jean's mass, making it equal to the horizon size. Since the gravitational collapse takes place on scales larger than the Jean's mass, overdense regions collapse while still larger than the horizon size to form separate universes¹⁷, and not black holes in our Universe. (This problem is now being investigated in detail with B. J. Carr.) This argument indicates that one might not expect to observe the Hawking effect today even if the early Universe were highly chaotic, unless 10^{15} -g black holes were present in the universe *ab initio*.

By generalising the calculations of ref. 24 it can be shown that if the number fluctuations in the black hole distribution satisfy

$$\frac{\delta N}{N} = N^{-n}$$

the perturbations will form discrete bound systems of mass M at a redshift

$$1 + z_b \sim 4 \times 10^{6-11n} \Omega^{3/4} t_i^{-1} \left(\frac{b}{1 M_\odot} \right)^n \left(\frac{M}{10^{11} M_\odot} \right)^{2/3-n} \quad (1)$$

where b is the initial mass of the hole and t_i the formation time. But, we know $b(t_i)$ in the isotropising model from the expression for the horizon size³⁵, $b \sim 10^4 t_i M_\odot$.

For an initially Poisson fluctuation, $n = \frac{1}{2}$, there is a minimum of parameters in equation (1) and the largest scales condense out first; where for partially correlated fluctuations, $n = 2/3$, all scales condense simultaneously. In both cases we can have $1 + z_b < 10$ for galaxy and cluster masses. This scheme of protogalaxy formation has a number of interesting points in its favour since the perturbations are not damped by photon diffusion in the radiation era, a process which smooths the interesting $\leq 10^{13} M_\odot$ scales from the spectrum of adiabatic fluctuations. Also, from equation (1) we see that there is a continuous scale of galaxy clustering and the existence of the galactic scale as a lower bound arises because gas dynamic processes are able to destroy the clustering on smaller scales. It is supposed that these non-gravitational effects imprint the characteristic scales and structure on galaxies rather than the precise spectral form of the density inhomogeneities³⁰.

There seems to be no observational evidence against a large number of small black holes having, say, the same mass spectrum and distribution as stars²⁴. The model might be open to observational test by the effect pointed out by Dahlbacka *et al.*²⁸. If gas which falls into a black hole cannot find a more efficient mechanism than electron ion collisions to maintain $T_e = T_{ion}$, (for example through turbulent or magnetic effects),

then a feature could be expected in the γ -ray background in the 10–20-MeV range.

Conclusions

I have tried to show that a partially chaotic model of the early universe can provide an explanation for the entropy and uniformity observed today together with a viable scheme of protogalaxy formation and clustering. The model has the following input. (1) The inhomogeneity is restricted to that class generated by shear fluctuations on all scales at the singularity. And (2), There is neutrino equilibrium, such that $t_{ve} < t_e$ which requires that the anisotropy, as measured by

$$A \equiv \left(\frac{\rho_B}{\rho_\gamma} \right)^{\frac{1}{2}}$$

is bounded above.

The restrictions (1) and (2) in conjunction describe 'equilibrium shear fluctuations'. Both these restrictions have phenomenological motivation. First, we know that the isotropy and finite entropy observed today limit the initial degree of chaos to a finite level³², and second, if there did not exist thermal equilibrium of the neutrino mediated weak interactions when $T \sim 10^{10}$ K then the synthesised abundances of helium and deuterium would be either indeterminate or non-existent¹⁴. The degree of generality admitted by the assumption (1) is difficult to assess precisely since no good criteria exist to determine physical cardinality. But as the influence of shear fluctuations becomes infinite as the singularity is approached whilst that of curvature fluctuations becomes negligible, the restriction (1) may in some ways be natural for a chaotic model.

Finally, two important and as yet undiscussed problems still loom large on the horizon of chaotic cosmology at a classical and a quantum level. We could ask why the discussion should be limited to baryon symmetric models of the initial state or indeed is the whole concept of a zero entropy (non-thermal) yet chaotic initial state a contradiction in terms in any case?

I thank Professor M. Rees, Dr B. Carr and Professor R. Matzner for constructive comments, and Drs D. W. Sciama and J. J. Binney for reading the manuscript. This work was supported by the SRC.

A physical interpretation of the Haicheng earthquake prediction

C. H. Scholz*

Earthquake Research Institute, University of Tokyo, Japan

A possible explanation for the successful prediction of the 1975 Haicheng earthquake is that the earthquake was triggered by a deformation front that propagated 1,000 km through NE China at a velocity of about 110 km yr⁻¹. The various phenomena that were used to predict the earthquake can be explained by the deformation front.

ON 4 February 1975, an earthquake of magnitude 7.3 occurred near Haicheng in Liaoning Province, north-east China. The earthquake had been accurately predicted by the Chinese, and thus was the first major earthquake to have been successfully predicted.

The prediction of the Haicheng earthquake took place in four stages—long-range, mid-range, short-range and imminent prediction^{1,2}—each stage representing a narrowing of the prediction window in space and time. Each stage was based on various observations judged to be precursory to an earthquake.

In 1970 a national meeting was held to discuss regions of particular seismic hazard within the People's Republic of China. That meeting followed the occurrence of a series of strong earthquakes that had begun with the two Hsingai earthquakes of 1966 and had culminated with a magnitude 7.4 even in the Pohai Gulf in 1969 (Fig. 1). It was postulated that these large earthquakes were migrating to the north-east, and as a result the area north of the Pohai Gulf, including Liaoning Province, was designated as a region in which a large earthquake, of magnitude 5 to 6, was to be expected in the future. The Jinzhou, Zhuanghe and Yalu River faults, all prominent NNE striking faults in southern Liaoning, were apparently recognised as the major structures along the NE trend of earthquake migration and were singled out for special attention. The result of this long-range prediction was an increase in scientific investigation in Liaoning Province, in particular, levelling along the Pohai coast, installation of new seismic stations and initiation of short level lines across the above mentioned faults.

In June 1974 another meeting was held to review the data collected as a result of the intensified studies made in the preceding 4 yr. At that meeting the prediction time span was shortened, to predict an event of magnitude 5–6 within 1–2 yr in the northern part of the Pohai Gulf. This was based on three main observations: (1) microearthquake activity had increased several-fold, beginning in late 1973, over the entire Liaoning Province. These were not foreshocks, being too widespread. This increase in seismicity was reported for the area enclosed by Shenyang, Tantung and Dairen, a triangular region 200 km on a side. (2) Levelling showed that the greatest gradients in vertical motion for the entire Pohai region occur in the Liaotung Peninsula. (3) Short level lines across the Jinzhou fault at Chin Hsien showed rapid vertical movements beginning in mid to late 1973.

The result of this prediction was to further intensify the scientific efforts, to begin a mass education programme to warn the general populace of the danger of a forthcoming earthquake and to begin organising amateur groups to report anomalous phenomena.

In mid-December 1974, a swarm of earthquakes occurred in the vicinity of Liaoyang, about 70 km north of the epicentre of the Haicheng earthquake. The principal shock was of magnitude 4.8 and was widely felt. This activity is unusual in this region of normally low seismicity, and following these earthquakes the Revolutionary Committee of Liaoning Province issued alerts concerning the possibility of a large future earthquake. Reports of anomalous behaviour of animals and water wells, which had increased before the Liaoyang earthquakes, continued to increase in the region Shenyang–Tantung–Dairen. In mid-January 1975, it was predicted that an earthquake of magnitude 5.5–6 would occur within this region in the first half of 1975. This further shortening of the time span of the prediction (but not of the span in space) seems to have been in response to the Liaoyang earthquakes and the increase in amateur observations of anomalies.

The foreshocks of the Haicheng earthquake began on 1 February, and peaked in the evening of 3 February. Ten of these events were greater than $M=3$, two greater than $M=4$, and were widely felt in the epicentral region. Also beginning on 1 February, observations of anomalous animal behaviour and water-well changes began to migrate to the vicinity of Haicheng and Yinkow (the epicentral region), a tilt anomaly at Shenyang began, and many anomalies in electrical resistivity and radon emanation were observed. These observations, particularly the foreshocks, led to narrowing the prediction area to the Haicheng–Yinkow area on the day of earthquake, and emergency measures were carried out as the earthquake was predicted to occur within 1–2 d.

The earthquake occurred on the evening of 4 February 1975. It was a left-lateral strike-slip event, on a north-west striking fault plane with an aftershock zone about 70 km

Fig. 1 Map of NE China, showing all earthquakes larger than $M=6$ since 1966, the localities mentioned in the text and the path of the deformation front.

long³. This fault plane had evidently not been previously recognised, and it has been suggested that it is a newly formed fault⁴.

Discussion

I have attempted briefly to sketch the observations and events that occurred before the earthquake. In one respect or another, most of the observed phenomena can be considered anomalous; what remains to be determined is which of these phenomena were truly precursory to the earthquake. That is, which phenomena had an actual physical connection with the earthquake and could therefore be used reliably to infer the coming of the earthquake.

When I first considered these problems I found that I could, based on conventional seismological thinking, readily dismiss as irrelevant virtually every allegedly precursory phenomenon save the foreshocks. Yet the prediction was made, and accurately, before the foreshocks. That this could have been done based on totally irrelevant observations seems very unlikely, since this would imply that it was fortuitous. But Liaoning Province is an area of normally low seismicity—it seems that in the 3,000 yr of Chinese history, the Haicheng earthquake is by far the largest earthquake ever to have occurred in Liaoning, only two earthquakes greater than magnitude 6 having occurred there in 3,000 yr. It is probably this fact that led the Chinese consistently to underestimate the size of the Haicheng earthquake: at all times they expected it to be less than magnitude 6. Thus barring the possibility of chance, I am forced to consider some rather unconventional possibilities to explain some of the forerunning phenomena.

Among the most interesting of the phenomena is the north-easterly migration of epicentres. That this migration occurred is beyond doubt, but what is important is whether or not there is some causative process responsible for the migration that would allow the Haicheng earthquake to be predicted by induction. Incidentally, the Chinese did not use pure induction. If they had, they would have predicted an earthquake of magnitude 6.5 to 7.5, the size of the other earthquakes in the series, and thereby would have correctly predicted the magnitude of the Haicheng earthquake. Instead, probably for the rather conservative reasons given above, they underestimated its magnitude.

Such migrations are known^{5,6}. One possible explanation for them might be that the change in the strain field produced by one earthquake triggers, with some time delay, the next shock. One cannot explain the north China migration so readily, however. The distance between the successive earthquakes is considerably larger than the fault lengths that can be associated with them, so that the strain change in one epicentral region resulting from the previous earthquakes in the series will be very small. Furthermore, the successive earthquakes did not occur on the same fault.

Two possibilities remain—either the migration was illusory or it occurred as a result of some migrating stress source of presumably deep-seated origin. In what follows, I refer to such a moving stress source as a 'deformation front'.

The second most interesting phenomenon was the strong increase in microearthquake activity that began in late 1973. This increase occurred over the entire province, so it could not have been caused directly by some process in the focal zone of the Haicheng earthquake, nor was it an artefact of increased instrumental coverage.

We are drawn, then, to suspect that if there is some relationship between the increase of microearthquake activity and the ensuing Haicheng earthquake, that it must have been caused by a rapid regional increase of stress level over all of Liaoning Province that later resulted as one of its manifestations in the Haicheng earthquake. This of course is not inconsistent with the earlier suggestion made to explain the earthquake migration, and that late

Fig. 2 Monthly tilt recorded at Shipengu. Recorded tilt is given by solid lines and dots. The average annual tilt cycle for 1972 and 1973 is shown as a dashed trace in 1974.

1973 marked the arrival of the stress source in Liaoning Province.

Regional levelling showed that vertical movements had been occurring at a steady rate before 1971 (ref. 2). Short baseline levelling repeated daily at Chin Hsien, however, showed an abrupt onset of tilt, down to the north-west, beginning in mid to late 1973, a time that coincides with the increase in seismicity. This levelling line crosses the Jinzhou fault, but no discontinuity in vertical movements occurred at the fault so that it apparently represents regional deformation. Levelling at Chuang-ho also is consistent with anomalously rapid vertical movements in the period 1970–74, but that at Cheng Tzu Tuan is inconsistent with this. Following the onset of tilt at Chin Hsien, a long-term tilt anomaly was observed with tiltmeters at Shipengu, beginning in June 1974, 8 months before the earthquake (Fig. 2).

Daily tilt rates at Shenyang, farther to the north, are shown in Fig. 3. A short-term anomaly was recorded with these instruments for 4 d before the earthquake. That anomaly was probably not due to deformation within the epicentral region, however, because no such anomaly was

Fig. 3 Daily tilt rates at Shenyang. The baseline assumed for integration is given by the horizontal lines. The integration was only carried to July because of the large tilt anomaly at the beginning of August, which was apparently caused by heavy rainfall.

observed at Shipengu, only 20 km from the epicentre, and no coseismic tilt was recorded at Shenyang. We notice a long-term tilt anomaly at Shenyang, however, marked by the very high tilt rates beginning in mid-December 1974, and lasting until April or May of 1975.

The three tilt anomalies are compared in Fig. 4, where the magnitude of the tilt vector is plotted against time, and the time scales are shifted so that the onset of the anomalies coincide. The time scales in Fig. 4 for Shipengu and Shenyang were expanded by factors of 3.8 and 5.7, respectively, with respect to Chin Hsien, and the magnitude reduced by a factor of four at Shenyang. The anomaly at Shipengu was taken as the difference of tilt recorded in 1974 from the average annual cycle of the previous 2 yr, indicated as the dashed trace in Fig. 2. The Shenyang anomaly was obtained by taking 10-d averages from the data shown in Fig. 3 and integrating them. A steady north-west drift was assumed to be the secular trend there, and was used as the baseline for integration. This procedure will result in the Shenyang tilt anomaly being contaminated with an unknown annual term, but the very good correlation with tilt at Chin Hsien (Fig. 4) shows that the anomaly is not masked. The details of the correlation are lost at Shipengu, where we have only monthly averages, but the overall shape of the anomaly there is also very similar to the others.

Fig. 4 Comparison of the tilt anomalies at three sites. The time scales at Shipengu (●) and Shenyang (×) were expanded by factors of 3.8 and 5.7, respectively, to that at Chin Hsien (○). The magnitude of the tilt vector is plotted. The magnitude of the anomaly at Shenyang has been reduced by a factor of 4.

The strong correlation of these three anomalies suggests that they are measures of the same phenomenon, a rapid regional deformation that propagated through Liaoning Province in a north-easterly direction.

Returning to the original hypothesis, if we assume that a deformation front propagated through China on a path indicated as the heavy dashed line in Fig. 1, we can show the sequence of events as a space-time diagram projected along that line (Fig. 5). There we can see that a deformation front moving at a velocity of about 110 km yr^{-1} can account for the increase of seismicity in Liaoning Province, the successive onset of tilt anomalies at Chin Hsien, Shipengu and Shenyang, and the triggering of the Liaoyang swarm and the Haicheng earthquake.

The details of the events in Liaoning Province are shown in a similar space-time plot in Fig. 6, which shows the magnitude of the tilt anomalies and, as arrows, the direction of tilt at several times during the passage of the deformation front. Initially, tilt was NNW at Chin Hsien, SSE at Shenyang and east at Shipengu. As the deformation front passed, all tilts rotated clockwise to the west. The Liaoyang swarm occurred just as the maxima arrived at that point, but the Haicheng earthquake occurred after the maxima had passed.

The compressed time scales at Shipengu and Shenyang relative to Chin Hsien indicate that the direction of motion

Fig. 5 A space-time diagram projected on a $N60^\circ E$ line.

of the deformation front turned to the east as it entered Liaoning Province in a way suggested in Fig. 1. This rotation was about an axis south of Chin Hsien, so that the propagation velocity of the front was greater by a factor of 3.8 at Shipengu and 5.7 at Shenyang than that at Chin Hsien. This also explains why the anomalies at Shipengu and Shenyang began after, but ended before, the anomaly at Chin Hsien and why the apparent velocity between these sites (200 km yr^{-1}) was greater than velocity deduced from the earthquake migration. Note also that the width of the deformation front was at least 300 km, and that this would include all the earthquake epicentres along the propagation path (Fig. 1).

Two other anomalous phenomena may also have been caused by the deformation front: a rapid rise in sea level of about 1 cm recorded by tide gauges on the Liaoning coast late in 1973, and an increase in magnetic field intensity in Liaoning relative to Peking that began in late 1973 or early 1974 and lasted until late 1975 (refs 1, 2).

There are only two inconsistencies, the lack of increased tilt at Chen Tzu Tuan, in the period 1970–74, and the 1976 Tangshan earthquake, which according to this model should have occurred late in 1968. The first can be explained if the levelling was done early in 1974 at Chen Tzu Tuan.

Fig. 6 Space-time diagram for Liaoning projected on a $N60^\circ E$ line. The magnitude of the tilt anomalies are shown against time, and the direction of the tilt vector indicated by arrows for several periods of time during the anomalies (up is north). The Liaoyang swarm is indicated by an open circle and the Haicheng earthquake by a closed circle.

With regard to the Tangshan earthquake, it should be pointed out that there are two conditions necessary for an earthquake to be triggered by a deformation front. The first is that a zone of high stress, in which an earthquake is already nearly imminent, lies within the path of the deformation front. The second is that the additional stress produced by the deformation front be additive (tensorially) to the pre-existing tectonic stress. The second condition may not have been met at Tangshan.

Conclusions

Although the Chinese did not use the anomalies at Shipengu and Shenyang in their prediction, I have shown that four of the observations upon which they based their predictions—the migration of epicentres, the increase of seismicity in Liaoning, the tilt at Chin Hsien and the Liaoyang swarm—may all be explained by a deformation front that later triggered the Haicheng earthquake.

I have, therefore, proposed a plausible hypothesis for connecting the phenomena used to make the prediction and the occurrence of the earthquake, the success of the prediction being the strongest argument for this plausibility. In doing so I have proposed the existence of a previously unknown phenomenon, the underlying mech-

anism of which is not understood. Deformation fronts have twice been directly observed to propagate between distant strain and tiltmeters in Japan^{7,8}, however. Migrations of large earthquakes, commonly at velocities between 80 and 270 km yr⁻¹ (ref. 6), may be caused by propagating deformation fronts, which may result from mantle stress waves^{9,10}. If this phenomenon is common, it may prove a powerful tool for earthquake prediction.

Much of this work was performed during a visit to China under the auspices of the Committee for Scholarly Communication with the People's Republic of China of the US National Academy of Sciences. The work was supported by NSF, NASA and a Sloan Fellowship. I thank K. Jacob, P. Richards, K. Mogi and K. Kasahara for reviews.

Control of grip and stick in cell adhesion through lateral relationships of membrane glycoproteins

David A. Rees, Clive W. Lloyd & David Thom

Biosciences Division, Unilever Research, Colworth/Welwyn Laboratory, Sharnbrook, Bedford, UK

Although cell adhesion to substrate must ultimately depend on 'sticking' by physical forces at the outer surface, we suggest that control is exercised through the 'grip' of the cytoskeleton. Our experiments indicate that grip can be relaxed by agents which release surface glycoproteins from some form of side-to-side organisation, and can be consolidated by suitable cross-linking to augment this organisation.

ONE of many stimulating challenges to our understanding of the function of animal cells, is to establish the mechanisms by which perturbations at the cell surface are expressed as changes in the cytoskeleton and vice versa. We show here that the response of fibroblast cells to contact with an inert substratum provides a convenient and appropriate system for investigation. When suspended cells settle on a favourable surface, the round shape undergoes a remarkable transformation to a more complex angular form which is flattened against the surface^{1–4}. This involves the formation of a three-dimensional meshwork of fibrillar proteins that is organised in relation to areas of adhesion^{3–5}, so that external contact has triggered a change from an unstructured to a highly organised cytoskeleton. The converse process of detachment from a substrate, for example by trypsin or chelating agents, is equally revealing because the sequence of intermediate stages shows that the primary event is usually the disintegration of a structured cytoskeleton^{6,7}. The cell body rounds up and withdraws from the substrate, leaving sites of adhesion intact; the process does not start

with dissolution of 'the glue' because only later does the cell float away. Further evidence that cell adhesion can be influenced (strengthened or weakened) by perturbing inner as well as outer structures, is that detachment is retarded when the intracellular level of cyclic AMP is artificially raised⁸ to enhance the stability of cytoskeletal elements⁹, and is accelerated by drugs which destabilise these elements^{6,10}. Thus it is important to distinguish between contributions to cell adhesion from internal structures, which we refer to as 'grip', and those from external structures which we refer to as 'stick'. Included in the 'stick' component are all manifestations of physical attraction between the cell surface and the substrate.

Preliminary characterisation of stick and grip

To investigate further whether fibroblast cells are detached from serum-coated glass by mechanisms that involve primarily the lesion of stick, or primarily the lesion of grip, we first used the interference reflection microscope. This instrument^{12–14} can visualise the zones of closest contact between the cell and substrate. These zones at first form a sharply defined pattern of subunits, each about 1–5 μm in area (Fig. 1c, f). Detachment by warm EGTA leaves the zones well defined (Fig. 1f, g) as the cell retracts and the membrane shows pronounced motility and blebbing. We interpret this as a disruption of cytoskeletal stiffening, so that the cell can now peel from the substrate even though the configuration is unaffected at each area of actual contact. From the theory of physical adhesion¹⁵ we know that, other things being equal, a deformable cell would be detached more readily than a stiffened cell because a

deformable body can detach by a peeling mode which is not open to a stiff one. Possible mechanisms that could cause peeling are the cell's own tension on individual sites (shown for example by the ability to deform flexible substrates¹⁶ and by the sharp recoil when adhesions are broken

Fig. 1 Photomicrographs of rat dermal fibroblasts (16C line, Colworth strain) as they are influenced by various conditions of detachment from a glass substrate. *a*, Scanning electron micrographs ($\times 952$) of cells detached from a glass medicine bottle after decanting the medium, washing twice with ice-cold Hank's balanced salts solution (HBSS, Ca^{2+} and Mg^{2+} free), chilling in this solution for 15 min, then shaking off with ice-cold EDTA (0.02% in the same salt solution). Cells were immediately fixed by mixing with an equal volume of 3% glutaraldehyde in Dulbecco's phosphate-buffered saline (PBS). After 30 min at 0°C , the cells were centrifuged, washed twice with PBS, post-fixed with osmium tetroxide and prepared for microscopy by critical point drying. *b*, Cells as they appear after typical dissociation with trypsin (0.05%)—EDTA (0.01%) in PBS, or with EGTA (0.05%) in Tris-buffered Ca^{2+} and Mg^{2+} free saline, at room temperature. Washing, fixing and processing as above. *c, d, e*, Stages in detachment by trypsin ($100\ \mu\text{g ml}^{-1}$ in HBSS at 23°C) from a glass coverslip, as seen with interference reflection optics. Parts of the cell that are in close apposition to the glass surface (that is, the adhesion sites) appear as dense black zones. *c*, Before exposure to trypsin; *d*, after exposure for 7 min; *e*, after exposure for 15 min. Note that attachment sites are at first sharply defined and later spread and become continuous. For space reasons, only a part of the underside of one cell is shown. *f, g*, Stages in detachment by ethylene glycol bis (β -aminoethyl ether)-N, N-tetraacetic acid (EGTA, 0.05% in Ca^{2+} and Mg^{2+} free HBSS at 37°C). *f*, Before exposure to EGTA; *g*, after exposure for 35 min. Note that the size, shape, and mutual relationship of many attachment sites after little while an area of the cell on the left of the photograph peels away from the substrate.

by micromanipulation⁷), pinching off the adhesive plaques in an exocytotic-like process (we have seen such plaques left behind by cells, remaining attached and enclosed in membrane vesicles) and/or through any turbulence in the medium. Turbulence should also be more effective in detaching deformable cells because they generally present a higher profile to the shearing liquid.

The mechanism of detachment by trypsin is a little more complicated. As the cell slowly rounds under the action of trypsin, it leaves retraction fibrils to the attachment zone^{6,7}. We have found by interference reflection microscopy (Fig. 1*c, d, e*) that the zones themselves become less well defined and eventually merge into a continuous grey background. Although this might seem to suggest that trypsin has dissolved 'the glue' at each area of contact, such an explanation would be insufficient for the results of further experiments. Using procedures described in the legend to Fig. 2, we found that less than 10% of 16C cells were detached from a monolayer on glass by incubation with trypsin ($10\ \mu\text{g ml}^{-1}$) on ice for 40 min. If the trypsin was replaced at 25 min by soybean trypsin inhibitor ($200\ \mu\text{g ml}^{-1}$), however, and after a further 10 min in ice, allowed to warm to 37°C , almost all the cells detached immediately. Cells did not detach when cooled in the absence of trypsin and then warmed. Therefore this mild trypsinisation can cause the lesion that normally leads to detachment but this lesion is only expressed as a result of a cellular response made in the absence of trypsin and which requires metabolic activity and/or membrane fluidity. We suggest that trypsin impairs the cell's ability to hold surface macromolecules in an appropriate configuration at each area of contact—hence these configurations disperse and the organised adhesion is replaced by a more amorphous contact over a larger area.

Our provisional conclusion is therefore that adhesion is controlled by cellular activity (that is, by grip) in at least two ways (1) by the overall stiffness and shape which determines how easily the cell is peeled away and (2) by holding macromolecules in the appropriate organised configuration at areas of contact with substrate. We refer to these controls as 'bracing grip' and 'focal grip' respectively. EGTA seems to cause detachment by an action on the former, whereas trypsin has an action on both.

In passing, we point out (as others have^{9,11}) that conditions can be devised for detachment by lesion of 'stick' as well as 'grip'. Cells detached with cold EDTA or cold trypsin in more severe conditions than described above, can have a flat and angular form which is different from the round shape of those detached under conditions more typical of subculturing procedures (Fig. 1*a, b*). This shows that 'stick' between cell and substrate can sometimes be dissolved or broken by shear before the full alterations in the cytoskeleton which would lead to cell rounding.

Surface glycoproteins in the expression of grip

To investigate further the mechanisms of lesion of fibroblast grip to the substrate, we used plant lectins. These di- or multivalent carbohydrate-binding proteins are known to cross-link carbohydrate components of the outer cell surface, including those glycoproteins which pierce the membrane and are associated with the cytoskeleton. Much evidence^{5,17,18-20} shows that the movement of lectin receptors can be accompanied and sometimes even directed by changes in the cytoskeleton. Our results lead to a conclusion that is opposite to this but complementary—that constraints on lectin receptors can consolidate the cytoskeleton in a form that preserves grip to the substrate.

Several authors^{17,22-25} have previously stated or implied that lectins can inhibit the detachment of cells by proteases and chelating agents. Lectins which apparently have this property are concanavalin A (con A)^{22,23,25}, phytohaemagglutinin^{17,22}, and the lectin of higher molecular weight

Fig. 2 Rate of detachment of fibroblasts from a glass substrate by trypsin, and its modification by con A. Established monolayers in glass Leighton tubes (without coverslips) were gently treated with the sequence of solutions indicated below. Each point of the graph represents the proportion of cells which could be detached (Coulter assay) by gently rolling the medium several times over the cells in a particular tube at a particular time, essentially as described by Johnson and Pastan⁸. *a*, Results for three sets of tubes of NIL 8 cells. Each tube of the first set (○), was gently washed with HBSS, incubated at 37 °C for 20 min with the same solution, then at 37 °C with crystalline trypsin (25 $\mu\text{g ml}^{-1}$) in HBSS. Each tube of the

second set (●), was gently washed with HBSS, incubated at 37 °C for 20 min with con A (100 $\mu\text{g ml}^{-1}$) in HBSS, then with trypsin as for the first set. Each of the third (■), was treated in the same way as the tubes of second set except that, after 15 min in trypsin, the cells were washed and incubated first with trypsin inhibitor (from soy bean, 100 $\mu\text{g ml}^{-1}$ in HBSS; 5 min at 37 °C) then with methyl α -D-mannoside (0.05 M in HBSS at 37 °C). All these operations and the results are shown schematically in Fig. 3. *b*, 16C cells were washed with HBSS, incubated at 37 °C with con A (100 $\mu\text{g ml}^{-1}$ in HBSS at 37 °C for 20 min), washed with HBSS and incubated with trypsin (25 $\mu\text{g ml}^{-1}$ in HBSS at 37 °C for 25 min), washed and flooded with trypsin inhibitor (from soy beans, 100 $\mu\text{g ml}^{-1}$ in HBSS) and then placed on ice for 10 min. The tubes were divided into two sets in this stage. One of the first set (○) were washed and incubated with ice-cold methyl α -D-mannopyranoside (0.05 M in HBSS). Tubes of the second (●) were washed and incubated with methyl β -D-galactoside (0.05 M) in HBSS. After 60 min, all cells (both sets) were carefully washed and flooded with ice-cold galactoside solution then allowed to warm to 37 °C. Note that the cold incubation with mannoside is necessary for subsequent detachment of cells in the warm with galactoside. In other control experiments, briefer treatment with mannoside (up to 30 min in the cold) was found to be insufficient for rapid detachment of a high proportion of cells when subsequently warmed with galactoside. The significant operations and results are shown schematically in Fig. 3.

from *Ricinus communis*²⁴. This has usually been explained in trivial terms, such as blocking of access to the detaching agent or the formation of lectin bridges between cell and substratum to replace the natural adhesions. We now describe experiments which show that these explanations are unlikely and then explore the implications of our own hypothesis, which has not previously been considered, namely, that adhesion is preserved by influencing the cytoskeleton through its relation with surface receptors that can be cross-linked by lectin.

Fig. 3 Schematic representation of key experiments with lectins and cell detachment. The top line shows that cells normally round up with warm trypsin, leaving retraction fibrils which are then withdrawn as the cell separates from the substrate. The vertical sequence shows that pretreatment with con A prevents subsequent rounding and detachment under the influence of trypsin; after removal of the trypsin, however, displacement of con A at 37 °C (see first loop) causes rounding and detachment proving that the lectin block was in the expression of the tryptic lesion rather than at the level of the action of trypsin. The last step in the vertical sequence shows that the displacement of lectin from trypsinised, protected cells is not in itself sufficient to cause detachment—subsequent warming is necessary to re-start metabolic activity and loosen the grip.

Exposure of cells in monolayer to trypsin caused rapid rounding and detachment but when they had been pre-incubated with con A, very few were detached by this treatment. Even vigorous shaking and further amounts of enzyme produced little further effect. Measurements with ¹²⁵I-labelled con A showed that 16C cells bound 7.2×10^7 molecules of lectin per cell, most of which (5.7×10^7 molecules per cell) was inhibited in the presence of 0.05 M α -D-mannopyranoside. Trypsinisation (25 $\mu\text{g ml}^{-1}$ for 20 min at 37 °C) removed 32% of the specifically bound lectin, presumably as a combined result of cleavage of the lectin itself and of a proportion of the receptors for it. The con A-protected trypsinised cells could be detached readily by brief incubation with methyl α -D-mannoside (Fig. 2a). Since this effect was specific in that it was not observed with methyl β -D-galactoside, it is attributable to the displacement of the remaining bound con A and hence of its protective influence. These observations (shown schematically in Fig. 3) prove that target molecules have been split by trypsin in the usual way but that detachment was prevented by the bound lectin; the explanation of lectin protection in terms of mere blockage of the action of trypsin, is therefore untenable. Similar results but with interesting differences in detail (unpublished work in this laboratory), were obtained with EGTA detachment. Evidently both agents can act on lectin-coated cells to cause whatever lesion would normally result in cell detachment but the usual expression of each lesion is prevented until con A is displaced. We have observed that some (but not all) other lectins can act analogously to con A. The effect is observed with all the normal and transformed cell lines that we have studied.

After the action of trypsin, cell attachment is not retained merely through lectin bridges to the substrate (Fig. 3). If this were so, removal of these bridges would leave cells free to be washed away—whereas we find that they are still firmly attached after prolonged incubation with methyl α -D-mannoside in the cold (Fig. 2b). Measurements with ¹²⁵I-con A confirmed that the cold incubation was effective in displacing 62% of the bound trypsin-resistant lectin, which is evidently sufficient to allow the cells to detach when metabolic activity is allowed to re-start by subsequent warming to 37 °C in the absence of hapten (Fig. 2b). Cells did not detach extensively after shorter incubations with cold mannoside followed by warming after its removal (for

Fig. 4 Typical electron micrographs of BHK cells seeded singly and grown on melanex coverslips for 48 h. After appropriate treatment (see below), cells were fixed for 30 min at 37 °C in 3% glutaraldehyde with 4% tannic acid in 0.1 M cacodylate buffer pH 7.3, then washed briefly in 0.1 M cacodylate, and postfixed with 1% osmium tetroxide in 0.1 M cacodylate pH 7.3 for 30 min at room temperature then 1% aqueous uranyl acetate for 30 min. Dehydration was through a graded series of ethanol concentrations. The sample was embedded in Araldite and sections were cut parallel to the substrate and stained with lead citrate. *a*, Control BHK cell. *b*, BHK cell after incubation at 37 °C with con A (100 $\mu\text{g ml}^{-1}$ in HBSS) for 20 min followed by trypsin (25 $\mu\text{g ml}^{-1}$ in HBSS) for 30 min. *c*, BHK cell after incubation at 37 °C with trypsin (25 $\mu\text{g ml}^{-1}$ in HBSS) for 10 min. MT, microtubules; MF, microfilament bundles. Bar 1 μm .

example, after 30 min which removed only 30% of bound trypsin-resistant lectin).

Having discounted two explanations, we are left with the possibility that lectin constrains the lateral arrangement of glycoproteins in a way that preserves the integrity of cytoskeletal components responsible for grip. The rapid reversal of protective action when lectin is displaced in our

Fig. 5 Highly schematic model for lateral organisation of cell surface glycoproteins for grip and stick in cell adhesion to substrate—note the reservations in the text on molecular realism. *a*, The suspended cell is not organised intra- or extracellularly for adhesion. *b*, *c*, In the attached cell, surface molecules (■) have been moved and organised at the sites of adhesion in a way that sets up the development of the cytoskeleton; they are held in this configuration by focal grip. The full development of cell morphology requires further surface molecules (□) to be organised at sites outside the adhesions, in the process by which cell membrane is drawn down between adhesions to flatten the cell and stiffen it against peeling, that is, to maintain bracing grip. Cell rounding and detachment can be initiated by lesions in the natural side-to-side associations of either set of surface glycoproteins (■ or □); expression of either lesion is prevented by lectins which, by cross-linking the glycoproteins, suitably constrain their positions.

experiments by glycoside hapten confirms that effective binding is indeed on the outer membrane surface, rather than some result that follows endocytosis.

The cytoskeleton in the expression of grip

To characterise the response of the cytoskeleton to detachment agents and lectins, we followed changes in BHK cells that had been seeded singly and allowed to spread for 48 h. Thin sections cut parallel to the substrate showed that areas of spread membrane contained long microtubules and bundles of microfilaments close to the underside of the cell (Fig. 4), and were bounded by a stretched, linear cell margin. By contrast, light microscopy showed trypsinised cells to be rounded and blebby, and thin sections confirmed this loss of surface tone. The convolution and infolding of the cell's margin is accompanied by progressive fragmentation and the eventual disappearance of microfilament bundles and microtubules prior to cell detachment (Fig. 4). When cells had been pretreated with con A, however, these trypsin-induced changes were arrested at an early stage (Fig. 4). Although cell shape may be altered, the margins remained generally smooth, long microtubules remained in most cells, and microfilament bundles could be observed in many.

From these experiments we can therefore confirm that pretreatment with con A prevents the action of trypsin from causing not only cell detachment but also the dissolution of cytoskeleton. There is some indication that con A might be more efficient in arresting the dispersal of microtubules than of microfilament bundles but the evidence for this is not clear cut. For the time being at least we prefer to regard these components as linked in a single system which is perturbed together by the agents we have used.

Model for glycoprotein relationships in stick and grip

We conclude that lectin cross-linking of carbohydrate chains on the outer surface can constrain the cell in a way that keeps it flattened and attached to the substrate, despite the action of agents that normally cause it to withdraw and detach. Whether the target sites for these agents are inside or outside the cell, the lesions they induce are not expressed until after the receptors have been released to rearrange in the plane of the membrane. At least two types of lesion can be involved in cell detachment: dispersal of the adhesive areas, for example by trypsin, and loosening of the cell body without changing the form and distribution of these areas, for example by EGTA. In our terms these represent lesions in focal grip and bracing grip respectively. The expression of both can be blocked by appropriate lectins.

We now propose a model to account for these results. In the suspended cell, surface receptors are not organised (Fig. 5, non-grip configuration). The development of the stiff, flat and attached form of the cell, however, requires lateral organisation of surface glycoproteins for the functions of focal grip and bracing grip (Fig. 5). Note that this representation is highly schematic and does not attempt to show the relative dimensions of molecular components of the surface and cytoskeleton (compare with ref. 26) or indeed to distinguish between different components of the cytoskeleton such as microfilament bundles and microtubules.

The relevant glycoproteins are exposed on the outer surface and pass through the lipid membrane to integrate with the cytoskeleton in such a way that ordering of the cytoskeleton necessarily involves an ordering of the lateral arrangement of these glycoproteins and likewise for dis-ordering. In the morphologically developed cell, specific side-to-side organisation of these glycoproteins is presumably maintained by natural bridging molecules, inside and/or

outside the membrane—and these are targets for agents which cause detachment. Such bridging molecules have yet to be characterised but submembranous, fibrillar proteins and external, endogenous, trypsin-sensitive, agglutinins^{28,29} could clearly be involved.

We thank Mrs T. Ogden for skilled technical support and Messrs C. G. Smith, M. Stubbs, C. Allcock and F. J. Judge, and Dr G. A. Dunn for help and advice with the microscopes.

letters to nature

Cosmological tests of general relativity

GENERAL relativity theory could be tested on a cosmological scale by measuring the Hubble constant and the deceleration parameter, if, in addition, everything could be known about the matter filling the universe. If, on the other hand, nothing could be presupposed about the matter content of the universe, general relativity could not be tested by measuring any number of time derivatives of the scale factor. But upon making the assumption of a universe filled with a non-interacting mixture of non-relativistic matter and radiation we can in principle test general relativity by measuring the first five derivatives of the scale factor. In the following, some general relations are presented using this assumption.

A reasonable model for the universe in a not too early stage of its development is the Robertson-Walker metric

$$ds^2 = -dt^2 + R^2(t) [(dr^2)/(1-kr^2) + r^2 d\Omega^2] \quad (1)$$

describing a homogeneous isotropic universe.

From general relativity theory it follows that the scale factor $R(t)$ obeys the Friedmann equation

$$\dot{R}^2 + k = \frac{8\pi G}{3} R \rho + \frac{\lambda}{3} R^2 \quad (2)$$

and conservation of energy and momentum is expressed by

$$\frac{d}{dR} (\rho R^3) = -3pR^2 \quad (3)$$

Here and throughout this paper we put $c = 1$; λ stands for the cosmological constant, while ρ and p denote the density and pressure of the matter content of the universe.

To test these equations we need observations. By measuring the luminosity distance or the angular diameter distance of remote objects as a function of redshift z , we can in principle determine the Hubble constant $H = \dot{R}/R$, the deceleration parameter $q = -\ddot{R}R/\dot{R}^2$, and an indefinite number of similar dimensionless parameters constructed from higher time derivatives¹. We shall use here, following Harrison²

$$Q = \frac{\ddot{R}R^2}{\dot{R}^3} \quad X = \frac{R^{(4)}R^3}{\dot{R}^4} \quad Y = \frac{R^{(5)}R^4}{\dot{R}^5} \quad (4)$$

(all evaluated at the present time, with signs which make them positive for vanishing λ , as will be shown). Without using Friedmann's equation (2), however, knowledge of any number of those parameters will not suffice to obtain the value of the present curvature $K = k/R^2$ (ref. 3). But even equations (2) and (3) are not sufficient without additional information about the equation of state, as can be seen as follows: by differentiating equation (2) N times we obtain $(N+1)$ equations for $(N+2)$ unknowns: ρ and its first N derivatives and λ .

A plausible form for the equation of state is obtained by assuming that at present the universe contains a non-interacting mixture of two forms of matter, non-relativistic matter with density ρ_m and ultra-relativistic matter with density ρ_r . Then

$$\left. \begin{aligned} \rho &= \rho_m + \rho_r \\ p &= \frac{1}{3} \rho_r \end{aligned} \right\} \quad (5)$$

For the non-relativistic matter, density, particle number conservation gives

$$\rho_m = A/R^3 \quad (6)$$

and thus with (3)

$$\rho_r = B/R^4 \quad (7)$$

where A and B are constant.

Now, carrying out three successive time differentiations of equation (2) leads with (2) to four equations for the newly introduced time derivative parameters. Solving these for the quantities K , λ , ρ_m and ρ_r , gives

$$K = \frac{1}{4} (-X + 4Q + Qq + 2q - 2) H^2 \quad (8)$$

$$\lambda = \frac{1}{4} (-X + 6Q + Qq - 6q) H^2 \quad (9)$$

$$\rho_m = \frac{1}{4\pi G} (-X + 3Q + Qq + 3q) H^2 \quad (10)$$

$$\rho_r = \frac{3}{32\pi G} (X - 2Q - Qq - 2q) H^2 \quad (11)$$

Differentiating (2) a fourth time finally leads to a relation

between the four parameters q , Q , X and Y which should hold if general relativity is valid

$$Y = 7X + 3Xq - 6Q + Q^2 - 7Qq - 3Qq^2 - 6q \quad (12)$$

This condition provides (in principle) a full test of the theory.

If less than five parameters measuring the time derivatives of the scale factor are known—as certainly will be the case in practice—still conditional relations can be derived between the various parameters. From equations (10) and (11) it follows that, since $\rho_m > 0$ and $\rho_r > 0$

$$Qq + 2(Q+q) < X < Qq + 3(Q+q) \quad (13)$$

a condition valid if only q , Q and X are known.

If X is not available either we introduce a new parameter α , still to be able to express the four quantities K , λ , ρ_m and ρ_r explicitly. For α we take

$$\alpha = \rho_r / (\rho_m + \rho_r) \quad 0 \leq \alpha \leq 1 \quad (14)$$

and we then obtain

$$K = [-1 + (3 + \alpha)/(3 + 5\alpha) Q - (4\alpha)/(3 + 5\alpha) q] H^2 \quad (15)$$

$$\rho = 1/8\pi G 6/(3 + 5\alpha)(Q + q) H^2 \quad (16)$$

$$\lambda = 3[(1 + \alpha)/(3 + 5\alpha) Q - (2 + 4\alpha)/(3 + 5\alpha) q] H^2 \quad (17)$$

Equation (16) gives us, as $\rho > 0$, the condition

$$Q + q > 0 \quad (18)$$

If we only know H and q —a situation which is at present striven for—it is regrettably no longer possible to write down even conditional equations, unless observational evidence of a different nature, for example, regarding the age of particular objects in the universe, is taken into account.

Figure 1 illustrates a classification, based on equations (15) and (16), of the structural and evolutionary properties of the universe, as depending on the values of q and Q , but with arbitrary λ . We can distinguish between domains of positive and negative ρ (the latter physically unrealistic), of $k = \pm 1$ (separated by a line $k = 0$), and the presence or absence of an initial and a final singularity (only with a final singularity the universe, at present expanding, has a finite lifetime). Depending on the value of α , the relative amount of matter which is present in the form of radiation, the borderlines between regions may change. Their equations are given in the two extreme cases $\alpha = 0$ and $\alpha = 1$ as

$$Q = q^2 + q + 1; \quad \alpha = 1 \quad (19)$$

$$Q = \frac{1}{3} \left[2q^2 + q + 2 + 2 \left(q^4 + \frac{8}{3}q^3 + 2q^2 - \frac{1}{3} \right)^{1/2} \right]; \quad \alpha = 0$$

Where the status of the universe depends on α , this is indicated by a double label as explained in the caption. Comparable diagrams have been published earlier by Stabell and Refsdal⁴. (As a referee commented, Fig. 3 of ref. 4, which is a σ - q diagram, is topologically very similar to Fig. 1 of this paper, as $\sigma = 4\pi G\rho/3H^2 \sim Q + q$.)

We can further simplify equations (8)–(11) by introducing two transformed time-derivative parameters

$$\left. \begin{aligned} \tilde{Q} &= Q + q \\ \tilde{X} &= X - Qq \end{aligned} \right\} \quad (20)$$

Then the right-hand side of equations (8)–(11) can be seen to

Fig. 1 Classification of structural and evolutionary properties of the universe in terms of Q and q with arbitrary λ . The shaded area is unphysical since $\rho < 0$ there. The symbols in the other regions have the following meaning: if one plus or minus sign is given, the value of the topological parameter k is $+1$ or -1 , respectively. A dot to the left of the sign denotes the presence of an initial singularity, and a dot to the right a final singularity. If a region has only one label, the conclusions follow irrespective of the value of α . If it bears two labels, the upper label denotes the situation for pure non-relativistic matter ($\alpha = 0$) and the lower one applies to the case of pure radiation ($\alpha = 1$). If $0 < \alpha < 1$, as is the case in our universe, the border lines lie always somewhere in between those given by the two extremes $\alpha = 0$ and $\alpha = 1$.

become linear expressions in the new parameters, where equation (12) transforms into

$$Y = 7\tilde{X} + 3\tilde{X}q - 6\tilde{Q} + (\tilde{Q} - q)^2 \quad (12')$$

The conditional relations (13) and (18) become very simple

$$2\tilde{Q} < \tilde{X} < 3\tilde{Q} \quad (13')$$

$$\tilde{Q} > 0 \quad (18')$$

We conclude that surprisingly simple relations can be derived, on the basis of rather general assumptions regarding the structure and matter content of the universe, between the 'physical' parameters of the universe ρ_m , ρ_r and λ , together with K , and the 'geometrical' parameters involving the first four time derivatives of the scale factor. Between the first five time derivatives a strict relation should hold if general relativity applies. This relation forms, in principle, a definite

test for the theory. If less than five parameters are known, but more than two, conditional relations can be derived.

I thank Professor H. G. van Bueren for helpful discussions.

Tugboat model for OB binaries, X-ray stars and pulsars

AN examination of the kinematical properties of binary OB stars, binary X-ray sources and pulsars suggests an evolutionary sequence linking an apparent low-velocity class of pulsars to the binary nature of their extreme Population I progenitors.

In a compilation of OB supergiants by Hutchings¹, 10 of the 65 stars listed are known binaries, and several more have variable velocities indicating a possible binary nature. Table 1 summarises the kinematical properties of these systems, grouping them according to the nature of their companions—four which have normal stars as secondaries (that is unevolved systems), three which have invisible, low-mass companions and three which are known X-ray sources presumably containing either a neutron star or a black hole. Comparison of columns 3 to 5 of Table 1 reveals distinct kinematical differences among these three groups. The unevolved systems have low space velocities and z -heights typical of extreme Population I objects. The group of stars with unseen, low-mass companions have similar z -heights, but much higher velocities. Their low- z values indicate that these velocities must have been acquired recently, for such speeds would indicate origins far (> 500 pc) from the plane if they were to be maintained on evolutionary timescales ($\sim 10^7$ yr). The velocities for the X-ray sources are not well determined, but their distances from the plane are larger than that for typical extreme Population I objects.

A careful comparison of the z -distribution of pulsars with their characteristic ages given by $\tau = P/2\dot{P}$ yields several clues about the kinematics and evolution of the pulsar population. The pulsar scale height $z_{r.m.s.} \approx 250$ pc (ref. 8) indicates that these objects must in general have velocities much larger than those of the massive OB stars ($z_{r.m.s.} \approx 80$ pc) from which they

are thought to originate. Recent measurements of pulsar proper motions^{9–12} have confirmed this conclusion, finding transverse velocities ranging from 50 km s^{-1} to well over 500 km s^{-1} . For $\tau < \sim 5 \times 10^6$ yr, the observed z -distribution, properly corrected for selection effects¹³, shows a rise of scale height with age that is consistent with the observed pulsar velocities. There is, however, a significant fraction of pulsars ($\sim 25\%$) with much larger characteristic ages, whose z -distribution implies absurdly low velocities (often with $v_z \ll 1 \text{ km s}^{-1}$). Proper motion measurements for several of these sources have yielded much higher velocities, showing that the characteristic age is not a true indicator of chronological age after a few Myr, thus confirming such suggestions made earlier from other evidence^{14,15}.

The discrepancy between dynamical and characteristic ages may be related to the decrease in the quantity $P\dot{P}$ ($\propto B^2 R^6 / I$) with time, perhaps as a result of magnetic field decay^{14,15}, alignment of the pulsar's magnetic and spin axes¹⁶, or some other process. One can model such a decay as an exponential decrease in $P\dot{P}$ with a characteristic timescale τ_D given by the time at which the characteristic and dynamical ages diverge ($\tau_D \sim 5 \times 10^6$ yr), and thus derive a new age estimate for each source, as well as the quantity $P_0\dot{P}_0$ proportional to the sources' initial magnetic field strength and moment of inertia. Comparison of $P_0\dot{P}_0$ with measured pulsar velocities shows that the three sources (Class A) with the lowest initial fields have $\langle v_t \rangle_A \lesssim 60 \text{ km s}^{-1}$ while the remaining nine sources (Class B) all have $v_t > 100 \text{ km s}^{-1}$ with $\langle v_t \rangle_B \sim 265 \text{ km s}^{-1}$. Furthermore, from the much larger sample of sources with measured values of P , we find that the 18 sources with small $P_0\dot{P}_0$ have a mean $|z|$ of ~ 75 pc, while the 59 sources with larger $P_0\dot{P}_0$ have $\langle |z| \rangle_B \sim 250$ pc (ref. 13).

We have proposed an explanation of these two dynamical classes of pulsars in terms of the different environments in which they originate¹³. The high-velocity, widely distributed sources are supposed to originate primarily from single stars. They were presumably accelerated by means of the asymmetric radiation force¹⁷, which provides a natural explanation for their wide range of velocities through small variations in the asymmetry coefficient. The second class of pulsars is presumed to arise in tightly bound, massive binaries where the asymmetric force is insufficient to unbind the system (the supernova explosion that produces the neutron star will not usually unbind the system either¹⁸). The force thus acts on the system as a whole, accelerating it to a velocity that is reduced from that which the free neutron star would have attained by the ratio of the stellar masses (typically $\lesssim 0.1$). The neutron star thus acts as a tugboat: it pulls an object more massive than itself, and thus its own velocity is diminished. When these neutron stars are eventually

released at the time of the second supernova, they will already be several Myr old. While passing through the X-ray binary stage they will have undergone a spin-down due to magnetospheric braking in the stellar wind of the companion and a subsequent spin-up to a period of $\lesssim 1$ s due to accretion torques (compare the evolutionary model for such massive systems of van den Heuvel¹⁹). Thus it is not surprising that their characteristic and dynamical ages disagree. They will be relatively low-velocity objects, with final space velocities composed of their former systemic and orbital velocities. The high orbital velocities observed for some of the neutron stars in X-ray binaries are apparently reduced by mass loss from the system before disruption. The system will apparently be disrupted when the second supernova occurs (the relative infrequency of binary pulsars attests to the high probability of disruption) and the second remnant neutron star will be accelerated by its asymmetric radiation force to a high velocity and join the Class B sources.

In this picture, the 10^3 -yr-old Crab pulsar at $z = 200$ pc and $v_r > 100$ km s⁻¹ is a result of the second supernova that disrupted the system which was carried to this height by the acceleration of the remnant from the earlier explosion. The binary pulsar system also apparently reached its present $z = 230$ pc in a similar manner, but the evolution of its companion has failed to disrupt the system. Many of the OB runaway stars which have typical kinematical ages of 1–5 Myr (ref. 20) may be binary systems that have been accelerated by the primary remnant, but have yet to reach the second supernova stage. The high velocity group 2 sources in Table 1 are a subset of these stars for which the existence of a low-mass companion has been established. They will turn on as X-ray sources a few Myr (ref. 19) later at higher z (group 3).

The fact that even the youngest pulsars and a large fraction²¹ ($\sim 30\%$) of the radio supernova remnants are found at $z > 100$ pc is consistent with a mechanism that drags some OB stars away from their birthplaces before they become supernovae.

The relative frequencies of OB binary systems, high latitude SNRs²¹, and Class A pulsars¹³ are all 20–30%; in addition, the total galactic population of Class A pulsars and systems able to evolve through the X-ray binary stage in $\sim 10^7$ yr are also in reasonable agreement. Future observations of more pulsar proper motions and searches for pulsars, X-ray sources and/or hidden, low-mass objects as companions to OB stars could better define this evolutionary picture.

Preliminary results from Solrad 11 γ -burst detectors

WE present here temporal and 0.2–2 MeV spectral data from two γ bursts observed on 12 June and 16 August 1976, by detectors on the Solrad 11A and 11B satellites. The 12 June burst showed evidence for structure on time scales down to ~ 10 ms throughout its lifetime, whereas the 16 August burst varied only with characteristic times longer than a few tenths of a second. A search for both slow and fast spectral variability gave negative results. Accurate absolute burst times are, however, not yet available, but since both bursts were also observed by at least one Vela satellite, positions are calculable and will be reported.

The Solrad 11A and 11B spacecraft were launched in March 1976, and are currently positioned on opposite sides of the Earth at heights of about 20 Earth radii. The γ -burst instrument on each spacecraft is omnidirectionally sensitive over the 0.2–2 MeV range and consists of a pair of $1\frac{1}{2}$ inch by $1\frac{1}{2}$ inch CsI scintillation detectors, the combined output of which drives circuitry designed for response only to rapid, transient events. A total average count rate during any 0.625 s interval of greater than about 7 sigma above background triggers the system, causing temporal and spectral information—including 0.6 s of pre-trigger data—to be stored in a memory for later telemetering to Earth. The temporal information is stored as data words which can be either of two types. For count rates below $1,092$ s⁻¹ the total number of counts accumulated per 14.65 ms is

Fig. 1 Count rate plotted against time for the 12 June burst. The time origin of the graphs is at $1903:40$ UT ± 2 s. *a*, Response of Vela 5A, which triggered at about the same time as Solrad 11A, but which does not store pre-trigger data. The full time resolution capability of this and the other Vela detectors is displayed here. *b*, Eight-channel (117.2 ms) time averages of Solrad 11A data for the same burst. *c*, Segments I and II of the Solrad data, but with 14.65 ms resolution.

recorded. At higher rates the time interval required to accumulate 16 counts is recorded with 0.3 ms resolution. Counts are simultaneously accumulated into four spectral channels covering the energy ranges of approximately 0.2–0.3, 0.3–0.4, 0.4–0.6, and 0.6–2.0 MeV. The contents of the spectral channels are read into the memory after each eight time accumulations, so the time resolution for spectral changes can range from 2.4 to 117.2 ms. Since there is no provision for in-flight energy calibration and the spacecraft mass complicates the detector response, the spectral data can be used to search for spectral variability, but not to obtain reliable spectral shapes.

Figure 1 shows count rate plotted against time for the burst of 12 June. Since the detector high voltage on Solrad 11B was turned off at the time of this burst, the only data available are from Solrad 11A and the Vela satellites. We have used two different time scales to show the overall burst structure and to give a higher time resolution view of selected portions of the burst. The 12 June burst was relatively intense, and was observed by γ -burst detectors on four Vela satellites. Figure 2 is a similar presentation of the 16 August burst. The response of 11A is low relative to 11B due to the probable malfunction of one of its two CsI detectors. This burst is small by Vela standards, having been just intense enough to trigger one Vela detector.

Fig. 2 Count rate plotted against time for the 16 August burst. The time origin is at 1615:31 UT $\pm$ 2 s. *a* and *b*, 117.2-ms averages of the responses of Solrad 11A and 11B, respectively. *c*, Section I of the Solrad 11B data replotted with 14.65-ms resolution.

The high time resolution graphs (Figs 1*c* and 2*c*) demonstrate an important difference in the signatures of the two bursts. The 12 June burst is very 'spiky', and shows clear evidence for structure on time scales as fast as ~ 10 ms. The fact that finer structure is not seen might simply be due to insufficient detector sensitivity, since the time resolution becomes better than 14.65 ms only for count rates higher than $1,092 \text{ s}^{-1}$. The 16 August burst, on the other hand, shows statistically significant structure only on time scales slower than a few tenths of a second. Since the two bursts were detected at about the same statistical level, the apparent difference between them is almost certainly real.

We have not explicitly shown rates in any of the separate spectral channels, but we have examined these data for evidence of spectral variability. Specifically, we carried out a χ^2 test of

the assumption that the hardness ratio—that is, the ratio of the flux in channels 3 and 4 to the flux in channels 1 and 2—remained constant throughout each burst. That is, we examined the quantity

$$\chi^2 = \sum_i \left(\frac{r_i - R}{\sigma_i} \right)^2$$

where r_i is the hardness ratio in a given spectral accumulation period, σ_i is an estimate of the standard deviation of r_i , and R is a free parameter that is the hardness ratio averaged over the burst. In several instances the probability distribution functions of the r_i differed significantly from the normal probability distribution, thus complicating the χ^2 analysis. (Note that a random variable that is the ratio of even normally distributed random variables is not approximately normally distributed unless the denominator in the ratio has a small fractional standard deviation.) Although we accounted for this effect in the worst cases—that is, r_i calculated from the smallest statistical samples—the χ^2 values obtained should be considered as only approximate indicators of goodness-of-fit.

To carry out the most sensitive possible search for both slow and fast variability, we carried out various time averages of the data before applying the χ^2 test. Basically, we found no compelling evidence for spectral variability, although for some of the time averages in the 0.25–1 s range χ^2 probabilities were below $\sim 10\%$. Since the spectral variability suspected on the basis of these probabilities was not correlated with the overall temporal structure of the bursts, however, we felt that the low probabilities were due partly to chance and partly to the statistical complications discussed above. The uncertainty in R for either burst was 5%, implying spectral constancy to within $\sim 10\%$ on several-second time scales.

In summary, we have seen evidence in one of two γ bursts for temporal structure on time scales down to ~ 10 ms. Higher detector sensitivity might have revealed faster time structure. We have also seen evidence that over the 0.2–2 MeV range the spectra of the two bursts were constant on several-second time scales to within $\sim 10\%$ during the observed—that is, most intense—portions of the bursts. This evidence favours theoretical burst models having the following features: The emission region can be at least as small as a white dwarf. The temporal smoothness of the 16 August burst suggests, however, that some burst sources might be much larger in at least one dimension, or that the γ rays sometimes undergo considerable dispersion—for example, by Compton scattering—between the emission region and the Earth. The source of the burst energy is not much affected by the burst itself, nor does it seem that the source is undergoing rapid physical change during the course of the burst. That is, we do not see evidence for physical processes such as rapid cooling or magnetic field changes that would be expected to cause spectral variations.

We thank Don Horan and Andy Fox of NRL and the crew at the Blossom Point tracking station for enabling us to obtain data in spite of formidable software problems. This research was supported by the US Energy Research and Development Administration.

Detection of ^4He in stratospheric particles gives evidence of extraterrestrial origin

WHIPPLE predicted the existence of micrometeorites, small interplanetary particles which enter the Earth's atmosphere without being melted by frictional heating¹. During the past 2 yr, large numbers of micrometre sized stratospheric particles have been collected which are believed to be extraterrestrial, because their elemental compositions closely match those of primitive meteorites^{2,3}. We report here the detection of large concentrations of ^4He in some of the particles. This not only suggests an exposure to solar wind, but also indicates that these particles are true micrometeorites in the sense that they were not strongly heated by entry into the atmosphere. Strong heating would have caused much of the helium to escape.

The particles were collected by an inertial impaction collector attached to a NASA U-2 aircraft flown at 20 km. The collector consisted of a 20-cm² oil-coated collection surface which was rammed through ambient air at the aircraft's cruise speed of 200 m s⁻¹. With the exception of aluminium oxide, a common stratospheric contaminant in this size range that is thought to come from solid fuel rocket propellant⁴, more than half the particles collected are believed to be of extraterrestrial origin. Nondestructive X-ray analyses have shown that most of these particles have abundances of Fe, Mg, Si, C, S, Ca, Al, Ni, Cr and Mn which closely match those of type C-1 carbonaceous chondrite meteorites^{2,3}. A total of 250 particles with diameters $\geq 4 \mu\text{m}$ have been collected by sampling about $3 \times 10^3 \text{ m}^3$ of stratospheric air.

Surfaces exposed to the interplanetary medium usually contain relatively large amounts of ^4He due to implantation of solar wind⁵. Ions from solar wind implant to depths of $\sim 500 \text{ \AA}$ in solid surfaces and form helium-rich layers on all exposed areas. Typical lunar soils have solar wind contents of the order of $0.1 \text{ cm}^3 \text{ (STP) g}^{-1}$. Lunar soil breccias and gas-rich meteorites also contain solar wind helium, but at generally lower levels due to diffusive losses and other processes. The flux of ^4He from the solar wind, as measured from the Apollo solar wind foil experiments⁶, varies from 4×10^6 to $18 \times 10^6 \text{ cm}^{-2} \text{ s}^{-1}$. From these measurements, it can be calculated that for $10\text{-}\mu\text{m}$ -sized grains exposed to solar wind at 1 AU, a saturation level

of helium would be reached on a time scale of 10–100 yr. The level of saturation depends on the grain temperature and mineralogy, but is expected to be in the range 0.01 to $1 \text{ cm}^3 \text{ (STP) g}^{-1}$.

To verify the extraterrestrial origin of the collected stratospheric particles, ten were analysed for helium using a high-sensitivity gas mass spectrometer. Seven of the ten provided measurable quantities of ^4He (Table 1). Although in several cases the helium concentration levels were quite high, the absolute amounts of helium measured were always small, of the order of 10^9 – 10^{10} atoms, which made it necessary to use the specialised mass spectrometer system and special techniques.

The stratospheric particles were prepared for helium analysis by mounting them individually in small aluminium foil sandwiches. Particles were transferred to the foils under a stereo microscope using a hand-held $8\text{-}\mu\text{m}$ diameter glass fibre. Silicone oil was used in the transfer and $\sim 10^{-10} \text{ g}$ of residual oil was retained on each particle. After particle transfer, each foil was folded to form a sandwich to enclose and protect the particle. The mass of aluminium ranged from 2×10^{-5} to $7 \times 10^{-5} \text{ g}$. In addition to the ten foil sandwiches which contained particles, fourteen sandwiches containing only the silicone oil drops were also prepared for use as control samples. For each set of mass spectrometer runs, the masses of the aluminium control foils closely matched the masses of the sample foils.

The mass spectrometer system we used⁶ involves no new concepts, but has refinements over other systems^{7–9}, giving simplicity of operation and an ability to detect low concentrations of helium in small specimens. Helium content was determined by melting and vaporising each aluminium foil packet in a resistance-heated tungsten coil under a vacuum. The released helium ($\sim 10^9$ atoms ^4He) was quickly passed over liquid nitrogen-cooled activated charcoal and non-vaporisable Al–Ti getters operated at room temperature⁶. Two minutes after vaporisation, a known fraction of the released helium gas was allowed directly into the mass spectrometer volume which had just been isolated from its vacuum pumps for 'static mode' operation. Absolute calibration of the instrument sensitivity was accomplished by adding a precisely known number of atoms of ^3He ($\sim 1 \times 10^{13}$ atoms) to the sample vacuum enclosure, and following the identical procedure to introduce the gas to the mass spectrometer. These low level ^3He spikes, which

Fig. 1 Scanning electron micrograph of stratospheric micrometeorite SP-14. The elemental abundances of the particle match type 1 carbonaceous chondrite meteorite values within a factor of two, and as revealed at higher magnification, the particle is an aggregate of $\sim 1,000$ -Å grains. The scale bar represents 5 μm .

were obtained by partitioning through calibrated volumes, were preferred to ^4He because of possible 'memory' effects that the latter isotope might contribute. The usually preferred 'spiking' procedure of immediately mixing the ^3He with the unknown ^4He gas sample was not followed because the ^3He spikes also contained $\sim 1 \times 10^{10}$ atoms of ^4He . A nearly constant mass discrimination of the mass spectrometer was repeatedly measured during each series of runs by analysing precisely known mixtures of ^3He and ^4He introduced from other vacuum enclosures.

The results of helium analyses of samples and controls are given in Table 1. The measurements were complicated slightly by a nearly constant small residual helium background displayed by the mass spectrometer system, resulting from a steady permeation of helium through glass components and from the desorption of helium from previous larger gas samples. Although this background changed slightly from day to day, it varied little within any given day as shown in column 5 of Table 1. The uncertainty in the measurement of this background ($\sim \pm 2 \times 10^8$ atoms ^4He) was the major source of uncertainty in the results.

The sample vacuum enclosure has mountings for four tungsten coils so that a combination of two samples and two controls could be vaporised in 2 h. Comparison of the data from the control samples (column 4) with background values (column 5) shows that no perceptible additional helium was released either by the control samples or by the heating of the tungsten coils. The results in column 3 for seven of the ten stratospheric particles, however, are clearly outside the range of the system background. The net ^4He released by these particles (column 6) ranged from a barely perceptible 4×10^8 atoms for sample SP-3 to a sizeable 2.7×10^{10} atoms for SP-14.

Measurements made of the ^3He released by the particles and controls, not listed in Table 1, were subject to the memory effects of the ^3He spikes. Consequently, net measured ^3He values of 1.9×10^9 and 4×10^8 atoms, respectively from samples SP-2 and SP-15 are not considered to be real. The other samples showed no measurable ^3He above background levels.

The final column in Table 1 lists helium concentrations ranging from 0.002 to 0.25 cm^3 (STP) g^{-1} . Such high concentrations confirm that the particles were extraterrestrial,

and that some or all of them were exposed to solar wind for at least 10–100 yr. Since solar wind ions are implanted only to depths of ~ 500 Å, the measurements also indicate that the particles existed as small particles in space and were not produced in the atmosphere by fragmentation of larger meteoroids.

The possibility that the observed helium could instead have been the product of decaying uranium seems remote. Production of the high level of helium found in sample SP-14, for example, would require a uranium concentration of 200 weight parts per million (w.p.p.m.) and a decay time of 4.6×10^9 yr. Although phosphate and zircons, sometimes found as inclusions in meteorites, can contain up to ~ 20 w.p.p.m. uranium, non-destructive X-ray analyses of these particles have shown their compositions closely to resemble chondritic meteorites which generally have uranium concentrations three orders of magnitude lower than the latter figure.

The compositional similarity of all ten particles, together with the observed presence of helium in seven of them suggests that all ten are of extraterrestrial origin. The absence of observable helium in three of the particles and the widely varying concentrations observed in the others can be ascribed to varying amounts of heating during entry into the atmosphere. It is estimated that with typical entry parameters a 10- μm particle will experience a thermal pulse of 500 °C or more and that this pulse will last for several seconds. The particles in this study which showed high helium concentrations after entry into the atmosphere are true micrometeorites in the sense that they have not experienced any substantial heating. Micrometeorites thus join meteorites and lunar samples as sources of extraterrestrial materials which can be analysed in the laboratory for clues to early Solar System processes. Because micrometeorites have probably cometary origin¹⁰ they are potentially a valuable source of primitive Solar System matter.

Pulsating aurora induced by upper atmospheric barium releases

AN effect which appeared to be pulsating aurora was observed to be associated with explosive releases of barium vapour near 250 km altitude, but only when the explosions were in the path of precipitating electrons associated with the visible aurora.

The primary purpose of this series of rocket experiments, launched from Poker Flat, Alaska ($65^{\circ} 77.5' \text{ N lat.}, 147^{\circ} 28.91' \text{ W long.}$) during March 1976, was the measurement of the magnitude and direction of electric fields and neutral winds in the auroral atmosphere¹. Each explosive charge was a standard 1.5 kg thermite mixture of Ba and CuO with an excess of Ba metal which was vaporised and dispersed by the thermite explosion². Traces of Sr, Na and Li were added to some of the charges in varying amounts, and an extensive set of spectrophotometric observations from the ground was planned to determine the effectiveness of each of these luminous, un-ionised species in tracing the upper atmospheric, neutral wind.

The two flights of interest here were made in the morning twilight on 27 and 28 March 1976, at about 1250 and 1300 UT, respectively. The approximate trajectory of the rockets is shown in Fig. 1 along with the location of the four releases and the ground stations. One difference between the two flights is that perigee on the 27 March flight was approximately 50 km higher than that for the 28 March flight.

Fig. 1 An elevation view of the rocket trajectory on 28 March 1976, in the geomagnetic meridian ($\sim 30^{\circ} \text{E}$ of true N) through the Poker Flat Research Range. Shown also are the approximate positions of the observing sites (Ester Dome: EDO, Poker Flat: PKR, Fort Yukon: FYU), the barium releases and the natural aurora. Figures in parentheses are release nos. PEDA, poleward edge of diffuse aurora.

Spectrophotometric observations were made from two locations, Ester Dome ($64^{\circ} 52.8' \text{ N lat.}, 148^{\circ} 3.4' \text{ W long.}$) and Poker Flat. Emission spectra were obtained for all the releases using a television spectrograph at Ester Dome. With this instrument, spectra between 4,000 and 8,000 Å at 40 Å resolution of chemical release clouds as well as intense aurorae are recorded on video tape at a rate of 30 frames per second. Focusing the sky on the entrance slit gives an angular spatial coverage of 8° (resolution: $< 0.5^{\circ}$)

Fig. 2 Observations of two atmospheric emissions and one neutral Ba emission associated with upper atmospheric Ba releases made on 28 March 1976, from Poker Flat, Alaska. The times of three of the four releases are indicated by arrows. The fourth release showed neither enhancement nor pulsation of the atmospheric emission. a, 6,110 Å BaI, TV spectrograph; b, 5,577 Å OI, TV spectrograph; c, 4,278 Å N_2^+ , photometer.

along the spectral line. At Poker Flat an optical interference filter photometer with an 8° field-of-view was used to observe 4,278 Å (N_2^+ ING) emission in each release and record the amount of ionisation of atmospheric constituents. Numerous other instruments making support observations included two wavelength-scanning Ebert-Fastie spectroimeters at Poker Flat, the Chatanika Incoherent Scatter Radar, and all-sky cameras, riometers and meridian scanning photometers at Poker Flat and Fort Yukon ($63^{\circ} 34' \text{ N lat.}, 145^{\circ} 17' \text{ W long.}$).

The morphology of the aurora on the occasion of both rocket flights was quite similar and characteristic of early morning aurorae in the Alaskan sector. Towards the equator was a large area of pulsating aurora and auroral glow. This area was terminated on the poleward side by a series of closely-spaced arcs appearing as striations in an E-W direction. Arc segments peeled off this boundary towards the pole with an overall eastward motion, forming so-called 'omega bands'. All of these features are part of what is referred to as the 'diffuse' aurora because of its apparent lack of structure to satellite-borne cameras³. The poleward, 'discrete' aurora consisted of weak, rayed arcs and arc segments. The location of the boundary between the diffuse and discrete auroral regions seemed to be relevant to the occurrence of the pulsating aurora effect which is the subject of this report. This location is shown schematically in Fig. 1.

On 28 March 1976, a distinct cloud of 5,577 Å [OI] emission was detected on the TV spectrograph located just below the bright Ba cloud on releases nos. 1 and 2, but not on nos 3 and 0. The photometer operated at Poker Flat observed 4,278 Å (N_2^+ ING) emission associated with each release as shown in Fig. 2, together with the 5,577 Å data from the TV spectrograph. It is apparent that there is an enhancement of both emissions associated with the first two bursts and that these emissions pulsate with roughly a 10 s period for approximately 60–100 s following the burst. The 4,278 Å pulsations were of the order of 100 rayleighs against a background of 1 kR. This would be produced by a flux of approximately $5 \times 10^8 \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$ of 500 eV electrons which would be deposited near the observed altitude of 200 km. Also from theory⁴, the corresponding intensity of 5,577 Å OI emission should be approximately 1 kR which is in reasonable agreement with TV spectrograph data, although that instrument is not calibrated on an absolute scale. No 5,577 Å OI emission was detected on March 1976, when all the clouds were poleward of the diffuse auroral boundary. Thus, because the enhancements occurred only when the chemical releases were above the diffuse aurora (or nearly so), it is tempting to assume that the presence of the diffuse aurora gives an indication of the conditions necessary to produce the pulsations.

Other geophysical effects associated with the early morning diffuse aurora were considerable absorption of galactic radio noise indicating D region ionisation produced by energetic auroral primary electrons, and electron densities in the E region $>10^5 \text{ cm}^{-3}$ observed by the Chatanika Radar. Table 1 summarises the observations from Poker Flat, indicating differences in the release environment which may be related to the production of the induced pulsations.

Table 1 Summary of observations during Ba releases

	27 March 1976 ~64.5° inv. lat.	28 March 1976 ~66° inv. lat.
Northern border of diffuse aurora		
D region radio wave absorption	Small	Large
E region electron density	$<10^4 \text{ cm}^{-3}$	$>10^5 \text{ cm}^{-3}$
F region electron density	$<10^4 \text{ cm}^{-3}$	$<10^4 \text{ cm}^{-3}$
Ionospheric electric fields	Weak, variable direction	Medium N-S directed, horizontal
Discrete aurora	Weak-rayed bands	None visible

The steady westward drift of ion clouds on 28 March indicated the existence of a N-S-directed, horizontal E field characteristic of early morning aurora. On 27 March the ion clouds striated and merged with the weak, discrete auroral bands indicating only variable, local E fields.

The TV spectrograph provides both spatial and spectral information on the development of the luminous cloud. The radius of the cloud was determined separately for the Li and Ba debris for release no. 3 on 27 March 1976 and both the Ba and Li clouds were observed to oscillate with a frequency near 1 Hz during the first 15 s after release. These high frequencies were not observed in the clouds which produced the auroral pulsations. Oscillations of longer periods (10 s) would be difficult to observe over the limited lifetime of the induced auroral pulsations. Thus, the observed high frequency oscillations may indicate the presence of lower frequency modes which could be intimately connected with the mechanisms producing the induced auroral pulsations.

Previous observations of enhanced auroral emissions and E region electron densities associated with F region Ba releases were made of the E region below the cloud by Stoffregen^{5,6} and although they showed the same overall time variation, there was no definite evidence of pulsations. In the case reported here, the diffuse aurora in the E region masked any enhancement which may have occurred and the observed pulsations were located just below the Ba cloud (~200 km altitude). Because the period of the pulsations was in the Alfvén or magnetoacoustic wave domain (10 s) and approximately that which is most often observed in the natural aurora at this latitude, attempts will be made in the near future to repeat the experiment in hopes of clarifying the mechanism for the natural production of pulsating aurora.

Configuration of the magnetic field and reconstruction of Pangaea in the Permian period

THE virtual geomagnetic poles of Laurasia and Gondwanaland in the Carboniferous and Permian periods diverge significantly when these continents are reassembled according to the fit calculated by Bullard *et al.*¹. Two interpretations have been offered: Briden *et al.*² explain these divergences by a magnetic field configuration very different from that of a geocentric axial dipole; Irving³ (and private communication), Van der Voo and French⁴ suggest a different reconstruction and it is shown here that these two interpretations are not incompatible and that the first may help the second.

I have developed a program which allows a spherical harmonic analysis of the palaeomagnetic field⁵ by a method similar to Kono's⁶. The magnetic field F_i at the point of colatitude θ_i and longitude ϕ_i is given by the equation

$$F_i = \sum G_j f_{ij}$$

where G_j is the expansion coefficient in spherical harmonics, and f_{ij} the vector whose components are trigonometric polynomial functions of θ_i and ϕ_i (notation used by Creer *et al.*⁷). A_i is the measured palaeomagnetic direction of unit length at the same point.

We need to minimise the following residual: $\Sigma(e_i)^2 = \Sigma(F_i/|F_i| - A_i)^2$ where $|F_i|$ is the modulus of F_i calculated starting from a first expansion. So a system of linear equations

Fig. 1 Proposed reconstruction. Transverse Mercator projection. The symbols indicate the location of the virtual geomagnetic poles that were used. Parallels and meridians are drawn every 30°.

◇ North America

□ South America

with unknowns G_j is given, the system solved and new values calculated for $|F_i|$, and the calculation repeated until the solution is stabilised.

The first eight terms of the expansion allow calculation of the orientation of the dipole (geomagnetic poles) and the position of its centre (see formulae in Creer *et al.*⁷). I have applied this method to the problem of the magnetic field in the Permian and I have grouped the palaeomagnetic results for neighbouring sections and then analysed the data thus obtained separately for the two aggregates Africa-South America (8 groups) and Europe-North America (14 groups).

If these continents are reassembled according to Bullard's fit, with Africa in its present position, the results are as follows:

	geomagnetic axis		centre of the offset dipole	
			distance	direction
Laurasia	46.5°N	227°E	1170 km	33°S 205°E
Gondwana	29°N	238°E	780 km	29°S 183°E

In both cases the angle between the direction of the geomagnetic axis and the direction of the centre of the offset dipole is about 80°. This configuration is quite different from the mean axial field observed in the Tertiary, but is similar to the present-day field. This lateral offset of the dipole allows us to resolve the problem of relative longitudes of the two supercontinents.

I have first superposed both geomagnetic poles and then rotated one continent around this common axis until the directions in which the dipoles are offset are coincident. A relative rotation of Europe and North America of -35° around a pole situated at 22°N and 25°E (with respect to Africa) is a satisfactory solution and the corresponding reconstruction is shown in Fig. 1, with the common geomagnetic axis placed on the geographic pole. This reconstruction is close to that proposed by Irving³ for the same period, but with different premises.

Isotopic evidence for dramatic climatic changes in East Africa during the Pleistocene

RAINFALL decreased dramatically in the Lake Turkana region 1.8-2.0 Myr ago and in the Olduvai Gorge region 0.5-0.6 Myr ago. This is documented by a major increase in the $\delta^{18}\text{O}$ values of pedogenic and groundwater carbonates at these times. The data suggest that meteoric water of the earlier, more humid climate was 2-4 per mil lower in ^{18}O content than modern waters of these regions.

A terrestrial stratigraphic record covering a large portion of the Pleistocene is found in several sedimentary basins in the eastern Rift zone of East Africa. We have examined the stable isotope variations through the Pleistocene at Olduvai Gorge in northern Tanzania and in the sediments surrounding Lake Turkana in northern Kenya (Fig. 1). Thirty-three samples of carbonates were analysed as were several samples of modern rain and lake waters from the two areas. Oxygen isotope compositions of carbonates are controlled by the

Fig. 1 Location map.

oxygen isotope compositions of the formation waters and by temperature¹. The oxygen isotope compositions of meteoric waters, in turn, are controlled by climatic factors^{2,3}. Consequently, isotopic analyses of groundwater carbonates provide excellent indicators of climatic conditions prevailing at their time of formation.

Three types of carbonates were analysed: pedogenic calcretes, pedogenic nodules, and groundwater nodules from lacustrine clays. The calcretes are impervious and represent sealed environments. This is documented by ^{14}C dating of 17 samples of upper Pleistocene and Holocene calcrete from Olduvai Gorge⁴. The dates fit with those determined on organic material from the same sequence and there is no overlap between the different stratigraphic levels. Further details of age relationships at Olduvai Gorge are documented by Hay⁴ and at Lake Turkana by Curtis *et al.*⁵ and Fitch and Miller⁶. Although some controversy still exists as to the age of the KBS Tuff at Lake Turkana, this tuff marks the climatic change discussed later. The Olduvai calcretes comprise both massive and laminated varieties, both of which were formed by meteoric water percolating downward through the soil column⁷. The

Fig. 2 A plot of $\delta^{18}\text{O}$ values of carbonates against age at Lake Turkana. The hatched area represents the isotopic compositions of theoretical carbonates in isotopic equilibrium with waters that have the range of $\delta^{18}\text{O}$ values for rain measured at Lake Turkana and Olduvai Gorge. The values were calculated for 25 °C using the equation of O'Neil *et al.*⁸. Stratigraphical relations are shown at the right.

lacustrine nodules appear relatively impervious and presumably also represent sealed environments; also, groundwater nodules occur in relatively impermeable clays.

In the section at Lake Turkana, samples older than 1.8 Myr have $\delta^{18}\text{O}$ values in the range +26.3 to +27.9, whereas those younger are relatively enriched with a $\delta^{18}\text{O}$ range of +30.4 to +33.0 (Fig. 2). At Olduvai Gorge, the Masek Beds which formed 0.4 to 0.6 Myr ago⁴ mark a similar transition from light to heavy carbonates: Beds I, II, III and IV have $\delta^{18}\text{O}$ values of +24.1 to +27.1 and the Ndutu, Naisiusiu and Holocene sediments have $\delta^{18}\text{O}$ values of +30.9 to +31.8 (Fig. 3). At Olduvai, a dramatic event took place during Masek time and perhaps a minor one occurred at the end of Bed I (1.7 Myr ago⁴). A general increase in $\delta^{13}\text{C}$ with $\delta^{18}\text{O}$ was also observed in both areas.

Fig. 3 As for Fig. 2, for Olduvai Gorge.

Craig⁹ has shown that East African waters are abnormally rich in the heavy isotopes of oxygen and hydrogen. The isotopic data do not fall on a line characteristic of world-wide meteoric water ($\delta D = 8\delta^{18}\text{O} + 10$) but are instead on a line characteristic of evaporating waters ($\delta D = 5\delta^{18}\text{O} + 10$). This is a result of the fact that the rain partially evaporates as it falls through the dry East African atmosphere. Analyses of five rain waters from Olduvai Gorge and Lake Turkana ranged in δD from +4.9 to +26.0 and in $\delta^{18}\text{O}$ from -0.4 to +3.5. The δD and $\delta^{18}\text{O}$ values of Lake Turkana and Lake Ndutu (west of Olduvai Gorge) are +37.1 and +5.84, and +41.7 and 6.7, respectively. These measurements concur with Craig's observations of unusually heavy waters in East Africa. Rain water has the lightest isotopic values of all the waters possibly involved in carbonate formation in this area. Modern waters from East Africa could not produce the relatively low $\delta^{18}\text{O}$ values observed in the older sediments unless soil and groundwater temperatures were 35–45 °C. This is completely unreasonable on the basis of faunal evidence. Therefore the soil and groundwaters from which the older carbonates precipitated originated from rainfall that was at least 2–4 per mil lower in ^{18}O content than found in modern waters of the region. This is favoured by lower evaporation rates and therefore implies that there was more rain in the past. Moreover, increased humidity might be expected to result in a decrease in temperature, which would cause a further decrease in $\delta^{18}\text{O}$ values of rainfall and groundwater. These results point to a drastic decrease in rainfall about 1.8–2.0 Myr ago at Lake Turkana and 0.5–0.6 Myr ago at Olduvai Gorge.

The Olduvai Beds contain faunal, lithologic and mineralogic evidence of increasing aridity from Bed I with a semi-arid climate, to the Masek Beds with an arid climate similar to that prevailing today. Bed I contains faunal

elements (e.g., the urocyclid slug) indicating moister conditions than any later deposit at Olduvai; the Masek Beds have forms characteristic of drier climates (e.g., the land snail *Limicolaria*)⁴. Extensive deposits of wind-worked tuffs occur from the Masek Beds to the present indicating drier conditions. The minerals formed by weathering in the Masek Beds (illite, zeolites, dawsonite) also indicate a climate drier than recorded previously at Olduvai Gorge⁴.

The sediments surrounding Lake Turkana also show evidence for a climatic change that coincides with the isotopic anomaly. Volcanic ash below the KBS Tuff (1.8 Myr old⁵) is altered to montmorillonite whereas that above it is altered to montmorillinite, chabazite and clinoptilolite. The shoreline of the lake that is older than 1.8 Myr was stable indicating that it probably was an open basin, whereas the fluctuating nature of the post-KBS shoreline and the presence of zeolites indicates that the lake periodically fell below overflow level.

The causes of the change in rainfall patterns are not clear from the study of these two areas. The climate of East Africa today is controlled by the intertropical convergence zone and the monsoons from the Indian Ocean^{10,11}. Any change in the intertropical convergence patterns, the relative positions and amount of highlands and their rain shadow effect, or in large bodies of water such as Lake Victoria, could have drastic effects on the amount of rainfall.

We are now determining the hydrogen and oxygen isotope compositions of hydrous authigenic minerals in an attempt to characterise more closely the isotopic composition of palaeometeoric waters in the region.

Field work was supported by the National Geographic Society, the National Science Foundation, the Penrose Fund, and the National Museum of Kenya. We thank L. D. White for his careful water analyses.

Location and age of Mesolithic coastal occupation sites on Oronsay, Inner Hebrides

THE existence of at least five Mesolithic occupation sites on the island of Oronsay, Inner Hebrides, has now been established (Fig. 1). Preliminary results of recent excavation of two of the sites were reported in 1971 (ref. 1). Since then further excavations have been made and the locations and ages of the sites in relation to the position of the shore line of the sea at the maximum of the Holocene marine transgression have been investigated. The results obtained suggest that the ages of some of the sites in relation to the former shore line cannot be established solely on stratigraphical

Fig. 1 Map of the Scottish Hebridean island of Oronsay (56° N, 6° W), showing the locations of known Mesolithic occupation sites and the position of the visible parts of the former shoreline mentioned in the text.

and altitudinal evidence but require supplementary information based on radiocarbon dating. It will be some time before the full details will be published, and so a short account of the results so far obtained is presented now.

The position of the former marine shore line differs markedly from that of the present coastline of the island of Oronsay (Fig. 1). The old shore line is obscured in places by blown sand, especially in the area between Caisteal nan Gillean and Cnoc Coig. It is possible, however, that at the maximum of the Holocene marine transgression Oronsay consisted of two main islands: a larger area of relatively high ground and a smaller low rocky area somewhat similar in aspect to the present Eilean nan Ron (Fig. 1) which supports a seal colony and is surrounded by limpet-inhabited rock skerries exposed at low tide. The islands may have been connected with each other at low tide as Oronsay is with Colonsay at present.

Measurement of high water level and low water level of spring tides in the summers of 1973, 1974, 1975 and 1976 at a number of stations along the eastern and western shores of Oronsay showed that present (summer) maximal tidal range varies between ~ 3.5 and 4.3 m, spring tidal range for practical purposes being 4.0 m, from -2.0 m to $+2.0$ m in relation to Ordnance Datum, Newlyn². If the tidal range around Oronsay at the time of the maximum of the Holocene marine transgression was approximately the same as at present, the contemporaneous Mean Tide Level (which is approximately the same as Mean Sea Level but is not precisely equal to it³) was $\sim +7$ m Ordnance Datum (OD) and the intertidal zone of that time was the area now standing at $\sim +5$ to $+9$ m OD. Measurements of the altitude of cobble debris deposited by modern severe storms (those of January and February 1974) suggests that along most of the coast of Oronsay similar storms at the maximum stand of the Holocene marine transgression may have thrown debris to locations that now occur up to $+11$ m OD. Storm debris might be expected to accumulate to somewhat higher levels than this on the crests of the cobble ridges that fringe the exposed southern peninsula of the former coast. The highest points on the crests of these ridges in fact occur at $\sim +11.4$ m OD (western ridge), $\sim +12.7$ m OD (southern ridge) and $\sim +13.1$ m OD (eastern ridge).

Three of the known Mesolithic occupation sites are located in positions that are above the highest probable high

water levels of ordinary spring tides and severe storms of the Holocene marine maximum. Occupation material of the Priors Midden occurs at levels between $\sim +12.8$ and $+14.3$ m OD. In the vicinity of the site the highest part of a (probably contemporaneous) marine cobble ridge occurs at $\sim +9.0$ m OD; other possibly contemporaneous beach deposits occur up to $\sim +11.9$ m OD. At Caisteal nan Gillean I occupation material is located on the crest of a sand mound between $\sim +16.0$ to $+17.3$ m OD and on the perimeter of the same mound at $\sim +11.1$ m OD. On the adjacent site of Caisteal nan Gillean II occupation material occurs at $\sim +12.5$ to $+15.5$ m OD, possibly fractionally lower, but certainly higher than $+11.0$ m OD, the probable upper limit reached by waters of severe storms when the Holocene sea stood at its highest level.

The two remaining known occupation sites, Cnoc Coig and Cnoc Sligeach, are located closer to the former shore line, both in altitude and position, than any of the other sites. Cnoc Coig is a low mound of (mainly) invertebrate shell debris, its crest at $\sim +10.2$ m OD, and the debris, up to ~ 1 m thick, rests on sand (possibly blown or beach sand) that in turn rests on solid rock. The shell mound is bordered

Fig. 2 Simplified vertical sections of recent excavations 30 m to the south of the crest of Cnoc Sligeach (left) and of excavations in 1913 by W. H. Bishop 20 m to the south-east of the crest of Cnoc Sligeach (right).

Table 1 Radiocarbon age determinations at Mesolithic occupation sites on Oronsay

Site	Nature of material dated	Position of sample within occupation debris	Lab no.	Age of sample in radiocarbon years (b.p.)
Caisteal nan Gilleann II	Wood charcoal { Humate abstract	Upper half of midden	Birm-346	4,920 ± 400
	Wood charcoal { After alkali pretreatment		Birm-347	5,150 ± 380
	Shells of <i>Patella vulgata</i>	Base of midden	Birm-348	5,450 ± 140
				5,570 ± 140 (outer)
Cnoc Coig	Wood charcoal	Base of midden	Birm-348	5,720 ± 140 (middle)
	Wood charcoal	Base of midden		5,850 ± 310 (inner)
	Wood charcoal	Base of midden	Q-1355	5,460 ± 65
	Wood charcoal	Base of midden	Q-1352	5,430 ± 130
Cnoc Sligeach	Wood charcoal	Upper part of midden	Q-1351	5,495 ± 75
	Wood charcoal	Upper part of midden	Q-1354	5,535 ± 140
	Wood charcoal	Base of midden	Q-1353	5,645 ± 80
	Valve of <i>Ostrea</i> sp.	Base of midden	GX-1903	5,015 ± 210
	Animal bone fragments (collagen)	Positions not known	GX-1904	5,755 ± 180
	Wood charcoal	Upper part of midden (composite sample)	BM-670	5,426 ± 159

on the north by a low rock exposure that was immediately adjacent to, if it did not itself form, the margin of the shore at the maximum of the Holocene marine transgression. The lowest level at which occupation material occurs at this site is ~ +9.0 m OD, approximately the same altitude as the estimated normal high water level on Oronsay at the maximum of the Holocene marine transgression. On this basis it is arguable that the Cnoc Coig site was occupied at the time of the marine maximum. Other evidence, however, argues strongly against this: the site is located on the seaward side of the rock exposure that (conjecturally) formed the contemporaneous shore line; fifty metres to the north of the site Holocene storm debris is present at levels up to ~ +9.5 m OD, but at the site itself no traces of storm debris in association with occupation material were found in the course of recent excavations. It may be concluded that the site certainly was not occupied during storms at the time of the marine maximum, and it is probable that the site was never occupied until after the sea had receded from its maximal position.

Occupation material at Cnoc Sligeach occurs near the crest of the mound at ~ +16.9 m OD, on the sides of the mound and around several centres located on the periphery of the mound. The lowest level at which substantial quantities of occupation material were found recently at this site was ~ +10.4 m OD, the material concerned (wood charcoal in association with shells of *Patella* sp. and *Littorina littorea*) occurring on the southern periphery of the mound and resting directly on storm-beach cobbles. In addition, a few small, diffuse, dark-brown or black patches, possibly of charcoal, were found sporadically distributed within the mixture of storm beach cobbles and pounded fragments of *Patella* sp. that extended downwards to solid rock at the same location (Fig. 2). The evidence is comparable with, but not precisely the same as, that described by Bishop⁴ whose extensive excavations on the south-eastern flank of the mound in 1913 demonstrated that the maximum altitude at which marine cobbles were deposited there was ~ +10.2 m OD. Bishop also noted that, at the site of his investigation, 'throughout the entire depth of this beach were found the same implements and remains as were found in the overlying shell refuse' (ref. 4). In Fig. 2 the vertical profile revealed by Bishop's excavations is compared with that of the recent investigations. It should be noted also that to the south-west of Cnoc Sligeach the storm-beach debris forms a narrow bar linking two rock knobs. Here the crest of the cobble and boulder debris reaches altitudes up to ~ +11.6 m OD. Collectively the evidence from locations on the south-western, the southern and the south-eastern periphery of Cnoc Sligeach suggests that the site was first occupied about the time of the Holocene marine maximum

or at what was only a short time after the maximum, when severe storms still were building cobble ridges up to levels of ~ +10 to +11 m OD.

The data presented above demonstrate that it is not possible to determine the age relationships between three of the known occupation sites (the Priory Midden and Caisteal nan Gilleann I and II) and the shore line at the (local) maximum of the Holocene marine transgression solely on the basis of stratigraphical and altitudinal evidence. They also suggest that the Cnoc Sligeach site may have been occupied slightly earlier than the Cnoc Coig site. Clearly another basis must be used to determine the age relationships among the five sites themselves and between each individual site and the shore line of the Holocene marine maximum.

Radiocarbon age determinations on occupation material are available from three of the sites (Table 1). The data point to the approximate contemporaneity of the occupation sites at Caisteal nan Gilleann II and Cnoc Coig; statistically no age difference can be established between Birm-347 on the one hand and Q-1353 and Q-1354 on the other (test used: $\Delta A \leq 2\sqrt{(\sigma A_1^2 + \sigma A_2^2)}$). The place of the Cnoc Sligeach site in the occupation chronology is uncertain as yet. This is because one of the three radiocarbon-dated samples was composite in nature (BM-670) and the exact provenances of the other two are not known (GX-1903 and GX-1904). Recent investigations yielded suitable material for radiocarbon dating from accurately identified positions at the Priory Midden, Caisteal nan Gilleann I and Cnoc Sligeach. When the samples have been dated it should be possible to establish the chronology of the sites in relation to each other and the former shore line by combining the evidence of radiocarbon dating with that provided by stratigraphical relationships and altitudinal positions.

I thank Dr P. A. Mellars for many helpful discussions, NERC and the University of Glasgow for meeting field-work expenses and Lord Strathcona for permission to work on Oronsay.

Spontaneous formation of bubbles in gas-supersaturated water

SPONTANEOUS nucleation of bubbles may occur in water subjected to heating¹⁻³, tensile stress⁴⁻⁶, or gas-supersaturation⁷⁻¹². Large discrepancies exist between the threshold nucleation conditions predicted theoretically and those indicated by empirical observations¹³. The theoretical approaches have been hampered by inadequate understanding of many of the submicroscopic and molecular properties of liquids, and experimental obstacles have included the always present and difficult to control interference from pre-existing nuclei. These problems have been most pronounced for nucleation induced by dissolved gas; indeed, nucleation thresholds for any gas/liquid system are unknown due to a lack of relevant empirical data, and no quantitative theories seem to exist.

Recent investigations of bubble formation at glass-water interfaces have indicated some minimum nucleation threshold limits for various gases in bulk water^{11,12}. More direct determinations of threshold values, obtained by cinemicrography, are reported here. The results raise some questions about the conventionally accepted relationship between surface tension and pressure in bubbles and the submicroscopic behaviour of water.

In the method used, water equilibrated at high argon gas pressures was decompressed to ambient, atmospheric pressure while it was observed for bubbles. The apparatus (Fig. 1) consisted of a 25 ml chamber for equilibration, A, connected to a 0.5 ml cuvette chamber, B, formed between

Fig. 1 Schematic diagram of the apparatus which consists of an equilibration chamber A containing a Pyrex cup with a magnetic stirring bar, a cuvette chamber for observations B, valves C and D and Millipore filter unit E. All parts in contact with water were made of stainless steel. A quartz lamp with a light-diffusing, heat-absorbing filter provided illumination.

optical type Pyrex windows (0.64 cm thick, 2.5 cm in diameter) separated by a flat stainless steel ring (0.30 cm thick, 1.40 cm inner diameter). The water in the transilluminated cuvette chamber could be photographed with a 16 mm, 64 frames s^{-1} , movie camera, equipped with an inverted lens of 2.5 cm focal length and an aperture of $f/11$; the lens to film distance was approximately 18 cm. The full frame coverage was about 0.14×0.10 cm, with about 0.02 cm usable depth of field. Before use, all important parts of the apparatus were dichromate-sulphuric acid cleaned and well rinsed. Double glass-distilled water was filtered through a

Millipore filter, pore size $0.45 \mu m$, before equilibration with argon of 99.99% purity. The gas was admitted to the chamber through the same type of filter. Some comparison experiments were performed without filtration.

When gas pressure is applied initially to the system, the water, still with little gas in it, is hydrostatically pressurised; this forces many potential pre-existing gas nuclei into solution. After equilibration at argon pressures ranging from 140 to 202 atm, the water was flushed under pressure through the cuvette chamber by slow and repeated copious bleedings at the valve on the top of the chamber outlet tube, with the assembly in the upright position as shown. The assembly was then turned to the horizontal position, and placed in a predetermined location relative to the camera lens, which had been focused on the nearest inner glass surface. Decompression to ambient pressure was performed over a period of 2-3 s with the camera running. A total of 27 such experiments were performed at room temperature ($20-22^\circ C$).

The films were examined frame by frame with $\times 20$ magnification. Bubbles could be detected at $5 \mu m$ diameter; those which arose in the water usually could be distinguished easily from those in focus and attached to the glass surface, as the former would usually be out of focus to varying degrees and would show some motion in unison due to a slight inevitable movement of the water caused by the volume expansion of the bubbles.

With the water saturated with argon at 155 atm and lower pressures, bubbles formed only occasionally within the relatively narrow field of the camera, and then only on the glass surface and at decompression pressures close to ambient value. At 158 atm saturation, some bubbles consistently formed on the glass surface. A few also could be observed in the bulk water, but there was some uncertainty as to whether they originated there. With progressively higher saturations the number of bubbles increased, with the largest increase by far occurring in the bulk water, and the bubbles started to form at higher decompression pressures, the higher the saturation. There was a notable synchronous appearance and even distribution of the bubbles in the water, with no coalescence in the early stages. At 165 atm, substantial numbers of bubbles (20-40 per μl) quite clearly developed in the bulk water. This was even more evident during decompression from higher saturations: at 177 atm, the majority of the bubbles (several hundred per μl) appeared in the water and, at 202 atm, at the time bubbles massively occurred in the water (several thousand per μl), relatively few bubbles could be observed on the glass surface.

Because of their presence in such large numbers, their synchronised appearance, and their even distribution, the bubbles observed in the water in general must be nucleated by a spontaneous, homogeneous process involving only the water and the gas dissolved in it, rather than arising from preformed gaseous nuclei in suspended motes or the interface of the motes *per se*. This is supported by the lack of any obvious effect when micropore filtering was eliminated, and also by the lack of any effect on the general cavitation behaviour of water after 1,000 atm hydrostatic prepressurization¹².

In the lower saturation range used here, where the number of bubbles is relatively small, motes may conceivably play a role. Therefore, it is difficult to establish with precision the minimum saturation which is necessary for spontaneous cavitation. It is difficult also to know accurately the supersaturation (that is, saturation pressure minus decompression pressure) which exists in the water at the moment of molecular nucleation, both because of the lack of detailed pressure measurements during decompression and the time delay between the moment of nucleation and the moment of first detection. However, considering all of these factors, the supersaturation for spontaneous nucleation by

argon in water is at least 150 atm, and probably between 155 and 160 atm. These values are the apparent supersaturations directly based on experimental readouts. The true gas tensions in the water may be significantly lower due to the increase in gas solubility which occurs when the pressure is released during decompression. This effect varies with the various gases¹⁴⁻¹⁸ and is not well known for argon. It is, therefore, difficult here to apply the proper correction for the hydrostatic pressure component in the effect.

The nucleation threshold value obtained here is about 30 atm higher than the supersaturation which can be maintained without any cavitation taking place either at glass interface or in the water¹¹. It is within the 100–1000 atm range suggested for spontaneous cavitation in water⁸, but below the value of 250 atm which has been implied from limited experimental observations with oxygen¹⁹.

Although cavitation in the bulk water so far has been directly examined for argon only, the cavitation properties for various gases at the glass–water interface were found to be dependent on the solubility of the gas, and hence its concentration rather than its tension^{11,12}. Thus, the onset of heavy interface cavitation occurred at identical supersaturations (that is, 145–150 atm) for argon and oxygen, two gases with very similar solubilities. For the less soluble nitrogen, 180–190 atm supersaturation was required for the same degree of cavitation. For helium, which has the lowest solubility in water, the value was in excess of 320 atm. Preliminary results on methane and nitrogen obtained by the present technique indicate that the same type of solubility relationship applies directly to the nucleation thresholds in bulk water.

Even a simplified analysis of the present results reveals some highly significant features of the nucleation process. At the critical saturation for spontaneous nucleation, the gas pressure of the nuclei, which would effectively equal the gas tension, must exceed the inward, collapsing force of the surface tension. The critical bubble radius (R) may be expressed (in cm) as: $R = 2\gamma/\Delta P$, where γ is the surface tension (dyn cm⁻¹), and ΔP is the difference (in μ bar) between the hydrostatic and the internal gas pressure. Using this conventionally accepted Laplace formula and a 'normal' surface tension (72.8 dyn cm⁻¹ at 20 °C), the minimum diameter of a stable or expanding nucleus would be 1.8×10^{-6} cm at 160 atm. Such a nucleus would contain at least 10^4 molecules, conservatively estimated by dividing the sphere volume (3.1×10^{-18} cm³) by the cube of intermolecular distance in the compressed gas phase (2.5×10^{-22} cm³). Considering the very dilute concentration of the dissolved gas at this pressure, only about 2×10^{-4} mol dm⁻³, the nearly instantaneous formation of such large gas bodies would be highly improbable, if not impossible. Aggregations brought about by fusions of unstable nuclei conceivably could reduce to some degree the dimensions for critical bubble size, but alone they could not significantly alleviate the basic problem. Also, the spontaneous formation of 'vapour' nuclei of the magnitude indicated above by the self-dispersion of water molecules must be dismissed even though void cavities involving only a few molecules have been postulated to exist in water (refs 9, 20–22).

How then does nucleation occur at the observed supersaturation values? Although it is as yet not possible to propose a quantitative model, or even to describe all of the factors involved, it appears that the surface tension at the gas–water boundary of the nucleus must be at least an order of magnitude lower than that obtained by extrapolation from macroscopic dimensions. The interaction between the compressed gas in the nucleus and the enveloping water would contribute to such a lowering²³, as would the phase boundary curvature effect²⁴, but these probably could not account for all of the effect. A less important factor which conceivably could aid the expansion of some small nuclei (and the collapse of others) would be the 'pres-

sure' fluctuations in their gas phase which consists of relatively few gas molecules. However, due to the ready diffusion of gas, no long-term imbalance could exist between the gas pressure and the gas tension in the water.

X-ray analysis of Co–C bond cleavage in the crystalline state

DURING serial structure analysis of cobaloxime derivatives¹, aimed at interpreting the catalytic capability of the asymmetric hydrogenation²⁻⁵, we have found that the crystal of *R*- α -cyanoethyl (*S*- α -methylbenzylamine)-cobaloxime changes its unit cell dimensions by X-ray exposure without degradation of a single crystal form. The rate of the change was so slow that it was possible to collect the intensity data for several intermediate stages. We have proved, by calculating electron density in each stage, that the change reflects the racemisation of the cyanoethyl group.

Figure 1 shows the changes of unit cell dimensions a , b , c and β with exposure time to the conventional MoK α radiation. The cell dimensions at 2 h after the initiation of the irradiation are $a=8.665(2)$, $b=13.485(3)$, $c=9.584(3)$ Å, $\beta=96.95(3)^\circ$ and $V=1111.6(5)$ Å³. The a and c axes contract slightly whereas the values of b and β increase to a considerable extent. The rate of change is rapid at very initial stage, but becomes moderately slow. They converge gradually to 8.637(2), 13.833(3), 9.539(2) Å, 99.07(3)° and 1125.5(4) Å³, respectively. After 22 d the changes are within the experimental errors. The space group, P2₁, remains unaltered. The reproducibility was confirmed by runs using three different crystals. The same results were obtained for the crystal of *S*- α -cyanoethyl (*R*- α -methylbenzylamine)-cobaloxime, which is the enantiomer of the present complex.

During these experiments, the appearance of the crystals gave no evidence of decomposition or degradation and the width of each reflection did not change appreciably. The peak and integrated intensities, however, varied to a considerable extent; they fell to an average 50% and 85% of initial values respectively in intermediate stages but fully recovered at the final stage. If the irradiation was interrupted, the change of the cell dimensions became undetectable. By resuming the irradiation, it continued as before.

The three-dimensional intensity data were collected at the stages denoted as A, B, C, D, E, F in Fig. 1. Before A, intensity data collection was unsuccessful. Figure 2 shows the crystal structure, projected along the *c* axis, deduced from the data at stage A. Fairly loose contacts are observed around the methyl of cyanoethyl group.

The electron density for stage B indicated that the occupancy of the methyl of the cyanoethyl group decreased significantly and a new peak appeared. Figure 3*a* shows a part of the composite difference Fourier map. The new peak is about twice as high as that of the hydrogen atom and is comparable to the depth of the trough at the position of the methyl group. Between stages B to F, the peak grows higher, and the trough becomes deeper. Figure 3*b* shows part of the composite electron density map at the final stage

Fig. 1 The change of the unit cell dimensions. A dark red crystal, $0.2 \times 0.2 \times 0.4$ mm, was mounted on a Rigaku automated four-circle diffractometer using MoK α radiation (40 kV, 20 mA; $\lambda = 0.71069$ Å) monochromatised by graphite. Cell dimensions were determined by least-squares analysis with 15 high-angle ($2\theta > 20^\circ$) reflections. Each value is shown with a point. The experiments were done at intervals of 2 h in the initial stage and done every day in the intermediate stages. By exposure over 22 d, each value fluctuated within its experimental error. E.s.d.s are 0.002–0.004 Å and 0.03–0.05°. At the initial stage the density calculated for $Z = 2$ is 1.388 g cm^{-3} , whereas the density observed by flotation is 1.388 g cm^{-3} . Intensity data were collected at six different stages denoted as A, B, C, D, E, F.

Fig. 2 The crystal structure at the stage A, projected along the *c* axis. Intensity data for independent reflections were collected with 2θ - ω scan, a scan rate of $8^\circ (2\theta) \text{ min}^{-1}$ and background counts of 5 s on both sides of the peak. Because 30 h were required for data collection, the orientation matrix of the crystal was redetermined for several times. A total of 2,069 reflections were measured within the limit $2\theta = 50^\circ$, of which 129 reflections for $|F_o| < 3\sigma(|F_o|)$ were considered unobserved. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares. Final *R* was 0.055 for 1,940 reflections. The structures for other stages were determined as described above.

F. The height of the new peak is approximately the same as that of the methyl group.

These observations indicate that some portion of the methyl groups is transferred to the position of the new peak so that disordering occurs with the methyl group. The position of the new peak corresponds approximately to that of the methyl group if the absolute configuration of the cyanoethyl group is converted from *R* to *S* with the cyano group fixed, although distorted from the ideal geometry because of the repulsion with the equatorial ligands. The least-squares calculations showed that the occupancy factors of *R* and *S* methyl groups are 0.75 and 0.25 respectively at the stage B and became equal at the final stage F.

In addition to the disordering of the methyl group, the molecule undergoes gradual translation. At the final stage it moves apart from the original position by 0.04 Å in the *a* and *c* directions. No significant changes were observed in bond distances and angles between the structures at the stages A and F.

Although the mechanism of the present transition in the crystalline state is not yet established, it is clear that any of

Fig. 3 *a*, Composite difference Fourier map along the *b* axis. Contour interval $0.1 \text{ e } \text{\AA}^{-3}$; negative contours broken. The analogous map was obtained at each of other stages, though the positive and negative peaks of the new peak and the methyl group respectively are enhanced and the hydrogen peaks are more obscure than those in the figure. In F_c calculation, the carbon atom of the methyl group is taken to have the occupancy factor of 1.0 and the hydrogen atoms of the methyl group are not included. The structures at the stage A are shown with the solid lines for comparison. *b*, The composite electron density map. Contour interval $1 \text{ e } \text{\AA}^{-3}$; inner contours of the cobalt atom are omitted for clarity. The black circles show the position of the corresponding atoms at the stage A. The asymmetric carbon and nitrogen atoms seem, from the spread and height of the peaks, to be slightly disordered.

four bonds, Co–C, NC–C, H_3C –C and H–C, would be cleaved in the transition; otherwise the asymmetric carbon of *R* configuration could not be converted to *S*. Schrauzer *et al.*⁶ and Giannotti *et al.*^{7–10} showed from the e.s.r. spectra that the irradiation of visible light ($\lambda > 420 \text{ nm}$) results in the homolytic cleavage of Co–C bond in the alkylamine-cobaloxime. It seems quite plausible that for the present complex the same reaction should occur in the secondary process initiated by X rays. Energy released by the bond cleavage might be given to the crystal lattice and contribute to causing topical melting. The cyanoethyl radical would be permitted to rotate to face the opposite side of the plane to the cobalt. This would result in the inversion of the configuration of the cyanoethyl group when the radical makes a bond to cobalt again. As it is quite probable that the racemic structure is more stable thermodynamically,

the growth of the racemic structure would continue without destroying a single crystal form—the racemers having almost identical cell dimensions—so that a whole crystal is converted into the racemic structure.

A physicochemical mechanism for magnetic field detection by migratory birds and homing pigeons

MIGRATORY birds and homing pigeons can apparently obtain directional information from the Earth's magnetic field. The effect is difficult to detect, and discussion of the possible process of magnetic field detection by birds seems so far to have foundered on the simple fact that the orientational effect of the Earth's magnetic field on a single electron spin associated with a molecule of animal tissue would be of the order 10^{-8} eV —almost certainly too small to be detectable biologically. Here I direct attention to a process which would overcome this basic problem, and which also seems to provide an explanation of all the main features of published data. It is a mechanism in principle only, however, and is discussed here in no more detail than is necessary to clarify the basic ideas and to provide a basis for further investigation.

There are three requirements that any proposed physicochemical mechanism for field detection must satisfy. First the mechanism must overcome the minuteness of the orientational energy produced by a magnetic field as small as that of the Earth's. Second, the mechanism must be basically unlikely, to account for the weakness of the observed response. Third, if the response is to display the necessary anisotropy (so that the bird prefers one direction to another), detection at the molecular level must take place in an ordered array of molecules, each with an anisotropic response to an applied magnetic field.

A mechanism which satisfies these requirements represents an application of optical pumping which depends on the presence and detection of radiation in the visible region of the spectrum. I propose therefore that magnetic field detection in birds takes place in the eye, in the molecules of the retina (a comparatively well-ordered structure spatially) as an adjunct to the normal processes of vision. Specifically, I propose an optical/r.f. (radio frequency) double resonance process involving the lowest excited molecular triplet state of (say) the rhodopsin molecule. The normal visual process begins with the absorption of a photon in the visible region. For various molecules such

an absorption is a singlet-singlet transition between the molecular ground state and a vibrationally broadened singlet excited state³. Neither of these states, being singlet ($S = 0$), have a magnetic moment, but the triplet states do, having total spin $S = 1$. For such states the anisotropy in the spin-spin dipolar interaction lifts the spin degeneracy in a manner most conveniently characterised by the effective spin-Hamiltonian parameters D and E (refs 4, 5). In conditions of continuous irradiation these triplet levels are dynamically populated through inter-system crossing from the singlet levels through spin-orbit interaction⁶, and experiment has shown that the relative populations of the three triplet states may be appreciably different from unity, depending on the details of symmetry and the relative probability of radiative transitions to the ground state^{6,7}. The relevance of this is that (1) the energy variation of triplet states with field is anisotropic, depending on field magnitude as well as the field direction relative to the principal axes of D and E ; (2) radiative transitions from these states back to the ground state are forbidden transitions and therefore weak; and (3) such transitions have definite polarisation relative to the molecular axes, and the intensity of each transition would depend on the relative populations of the triplet states. If, therefore, the next stage of the detection process were able to monitor radiative intensity at a particular polarisation, and if the relative populations of the triplet states were to vary with magnetic field direction, the detection process would be possible in principle. For this latter requirement we have to postulate first that the parameters D and E produce the necessary magnetic anisotropy, and second, that at least one of the anisotropic $S = 1$ splittings comes into resonance with some internal relaxation process having a frequency around 3 MHz (to satisfy $h\nu_{rr} = g\beta B$, with $B \approx 10^{-4}$ T). It would be premature to try to specify the possibilities for this at present; optical pumping is a double resonance process and therefore depends not only on the existence of such a resonance but also on various other relaxation rates happening to be within a suitable range. Typical values for D and E for various molecules already studied^{4,6} are two to three orders of magnitude too large, though the requirement here is merely that E should be negligible compared with splittings that would be produced by the Earth's field, while D could take any value. Radiationless decay rates vary widely, but tend to be too fast rather than too slow. The model does therefore face some considerable difficulties in detail, though direct evidence for rhodopsin, or whatever molecule is active in the living creature, is lacking at present. One might therefore have been reluctant to postulate that birds were able to detect the Earth's field, but here one is faced with the fact that they do. I now turn to a review of the experimental data in the light of the above model.

The main findings seem to be: (1) response to field is evident over a wide range of illumination—daytime overcast¹¹ to starlit sky¹⁷—but not, so far as I am aware, in total darkness (see (7) below). This is consistent with a detection process based on the normal visual process. (2) The response is much weaker than other directional clues (though stronger, apparently, than stellar constellation information¹⁷) and is difficult to detect experimentally. This is consistent with the electric-dipole forbidden nature of triplet state radiative decay, and the probability of competing radiationless decay processes. (3) The response to magnetic field is axial rather than polar. That is, birds show sensitivity to the angle of dip rather than the N-S direction of the field⁸⁻¹⁰. This is consistent with a resonance process (though there are slight difficulties concerned with the detection of a particular polarisation in the next stage of the process) and is perhaps the best evidence there is for the proposed model, particularly when taken together with the fact that (4) the response to magnetic field reaches a peak for fields comparable with the Earth's, falling off at both lower and higher fields⁹. (5) The response to field disappears temporarily if the field is altered a little ($\sim 20\%$), but returns if the birds remain in the altered field for a day or two⁹. This is consistent with the detection process taking place in a directionally ordered

structure (such as the retina) and where the molecular response to field is axial; that is only the field component parallel to the molecular axis matters, as in the case $D \gg E$. In this case for a particular eye orientation the resonance condition would be satisfied on particular areas of the retina. Altering the field would shift the resonance condition to some other region of the retina and confuse the bird initially. A day later, however, it could have learnt to respond to the altered cue. (6) Birds and a large number of other creatures are able to detect polarisation of light¹². This need not necessarily have its origin in triplet state radiative decay, but it is a requirement of the proposed model. (7) Attempts to operantly condition pigeons to magnetic field have so far failed to produce unambiguous results^{13,14}. A possible reason for this may be found (thanks to Professor Keeton for providing further details of experiments from ref. 14) in the lighting level during the experiments. Birds go to sleep in total darkness⁹, while normal laboratory lighting is too bright for operant conditioning, so the light level is therefore used to set the bird's level of awareness to a hopefully suitable level for the experiment. If, however, field detection does take place in the eye, there is some possibility of 'tuning out' precisely the effect one is seeking, by using the light level in this manner. (8) There is somewhat sketchy evidence that birds lose their orientation in the vicinity of radar installations¹⁵. This is consistent with resonances in the GHz region due to the D splitting of the triplet state, which would tend to disturb the equilibrium due to the internal r.f. resonance as postulated.

Thus, in conclusion, optical pumping overcomes the basic problem faced by any proposed model for field detection in biological systems, and also the excited triplet state provides for the anisotropy which is essential if such detection is to be useful directionally. Though the requirements placed on the parameters D and E and all the appropriate relaxation processes are rather stringent, the straightforward explanation which this model provides for the existing data does provide some grounds for optimism. The questions it raises are obvious—is vision essential to magnetic field detection? Can the physico-chemical requirements be satisfied? Behaviourally, it might be interesting to conduct the directed-perching type of experiment⁹ in monochromatic light at long wavelengths, in the hope of modifying the excitation transfer probability to the lowest excited triplet state. Finally, nothing in the proposed mechanism is specific to birds, rather than other creatures which have likewise shown sensitivity to the Earth's magnetic field¹⁶.

I thank Professors G. V. T. Matthews, Sir Denys Wilkinson and W. T. Keeton for discussions and encouragement. Dr D. T. Edmonds provided useful ideas on relaxation processes, and Miss M. M. Davidson assisted in the literature research. I am also grateful to the British Broadcasting Corporation, whose Horizon programme on Professor Keeton's researches first stimulated my interest in the problem.

Sources of sulphur in rain collected below a wheat canopy

VEGETATION plays an important role in the cycle of sulphur between the atmosphere and the soil¹⁻⁴. We have measured the quantity of sulphur in rain collected below a maturing wheat canopy. This sulphur has three sources: first, the atmosphere, from which falling rain gains SO₂ and sulphate; second, leaf surfaces, from which rain washes sulphur which was previously deposited by turbulent transfer ('dry deposition'), and third, leaf tissue, from which rain leaches sulphur⁵. We have now deduced from field and laboratory measurements that leaching supplied nearly 90% of the sulphur gained by rain as it fell through the wheat canopy. Only a small fraction of sulphur which had been dry-deposited on the surface of leaves could be washed off.

The measurements were made in June, July and August 1975 in a 6.9-ha field of winter wheat (variety Maris Huntsman) growing at Sutton Bonington (52.8°N, 1.25°W), a rural area within an industrial region. Rainfall above the canopy was collected at 12 sites in the field in polyethylene funnels, diameter 14 cm, which drained into glass bottles. At each site, throughfall below the canopy was collected in polyvinyl chloride guttering, 2 m × 7 cm, laid along the rows and draining into glass bottles. These linear gauges were calibrated over short grass by comparison with a standard rain gauge. The funnels and gutters were wiped with tissues soaked in distilled water at least every 4 d and whenever possible immediately before rain fell. This practice may lead to underestimation of the quantity of rain received in light showers but it minimises analytical errors from contamination⁶. A linear regression of throughfall, T (mm), against rainfall, R (mm), for 11 events yielded $T = 0.50R - 0.036$ ($r = 0.99$). Experiments with artificial rain indicated that the canopy storage capacity immediately after rain was 0.5 mm. We were unable to measure stemflow, S , so we assumed that it accounted for the residual, that is $R - 0.5 = S + T$. The large stemflow component is consistent with the upright structure of the crop and the compositions of stemflow and throughfall were assumed to be identical because both passed over similar leaf surfaces.

The wheat crop was sampled at weekly intervals by collecting tops from four randomly selected rows, 2 m long, and roots from four soil cores to 2-m depth. The four top samples were digested individually; roots were washed free of soil and digested in bulk⁷. The sulphur contents of digested plant samples and of rainfall were determined by precipitation of barium sulphate. Washing followed by redissolution of the precipitate in EDTA facilitated the measurement of barium by atomic absorption spectrophotometry.

Fig. 1 Sulphur content of winter wheat in 1975 expressed as sulphur per unit ground area ●. Roots; ○. roots plus tops. Anthesis was on 15 June and harvest on 5 August.

Table 1 shows that after rain additional sulphur was always found in water collected below the canopy. The excess consists of dry deposition washed from leaf surfaces and leachate from leaf tissue. The contributions from each source during the whole period can be assessed as follows.

Fowler^{2,8} made a detailed study of dry deposition of SO₂ on wheat growing in the same field in 1974 and deduced typical values of the deposition velocity, v_d , to wet and dry leaf surfaces⁸. The mass, M , of sulphur dioxide deposited in time, t , on leaves covering unit ground area is $M = v_d \chi t$ where χ is the SO₂ concentration above the surface. While our measurements were being made, the mean value of χ at a nearby site was $32 \mu\text{g m}^{-3}$. Meteorological observations indicated that leaves were wet (mainly with dew) for about 15% of the 66-d period. Using Fowler's values $v_d = 1.5 \text{ mm s}^{-1}$ (dry) and 10 mm s^{-1} (wet) we estimate that M corresponded to about 250 mg S m^{-2} during the whole period, that is deposition on the cuticle was similar in magnitude to the 236 mg m^{-2} additional sulphur found below the canopy (Table 1).

To estimate the fraction of deposited sulphur which could later be washed off the cuticle, we exposed leaves of senescent wheat plants growing in pots to radioactive ³⁵SO₂, removed the leaves at intervals ranging from 10 min to 8 d, and washed leaf surfaces thoroughly with distilled water. Stomata in senescent leaves present a large resistance to gas exchange⁹ so we assume that most of the radioactive sulphur was on the cuticle. The fraction of total activity which could be washed off had a mean of 0.13 and ranged from 0.04 to 0.19. If the same mean figure is valid in the field, dry deposition washed from leaves supplied only about 30 mg S m^{-2} of the additional 236 mg S m^{-2} recorded below the canopy (Table 1). Garland and Branson found a similar fractional washoff from pine shoots exposed to ³⁵SO₂ (ref. 10).

Table 1 Sulphur contents of rainfall and throughfall below a wheat canopy

Period of rainfall	Rainfall (mm)	S content of rain ($\mu\text{g ml}^{-1}$)	S input to canopy in rain (mg m^{-2} ground area)	S content of throughfall ($\mu\text{g ml}^{-1}$)	S output from canopy by throughfall and stemflow (mg m^{-2} ground area)
2-3 June	4.3	$3.1 \pm 0.2^*$	13.3	3.6 ± 0.2	13.3
15-16	10.7	3.3 ± 0.3	35.3	5.0 ± 0.4	51.0
8-10 July	1.6	13.9 ± 1.1	22.4	34.3 ± 2.6	37.7
10-13	5.6	3.4 ± 0.2	19.0	24.8 ± 2.6	126.5
13-15	9.1	2.0 ± 0.1	18.2	6.8 ± 0.7	58.5

			Total 205.8		Total 442.1
					Additional sulphur 236 mg m^{-2} ground area

*s.e.m.

Figure 1 shows the results of the sulphur analysis of whole plants and roots expressed as sulphur per unit ground area. Clearly sulphur losses from the plants after anthesis (15 June) greatly exceeded sulphur additions measured in throughfall. The sulphur content of the tops decreased by about 40% after this time, but Table 1 shows that leaching from leaves accounted for only about one third of the sulphur lost. Because sulphur did not accumulate in roots we conclude that it was removed by other mechanisms as well as by leaching in rain. Exudation of sulphur from roots of plants growing in solution and exposed to SO_2 has been reported¹¹⁻¹³. Knowles and Watkin¹⁴ observed large losses of potassium (approximately 50% of maximum content) from wheat plants after anthesis and they postulated an efflux through the roots to the soil. A similar efflux of sulphur seems the most likely explanation of our results. Emission of gaseous sulphur compounds from leaves (reported for tomato plants¹⁵ and pine needles¹⁶) is another possibility.

Our measurements and calculations show that leaching of plant sulphur by rain was the main source of additional sulphur in throughfall, and that most sulphur dry-deposited on leaf surfaces remained fixed there. Current studies in Scandinavia aim to deduce deposition velocities for SO_2 to forests by ascribing part of the excess sulphur in throughfall to deposited sulphur washed from leaf surfaces³. Our results show that this technique would be highly inaccurate for a maturing wheat crop, and it is clearly desirable to make further studies with vegetation of other ages and species to establish the pathways in the sulphur cycle more clearly.

We thank D. V. Crawford, J. A. Garland, J. R. Branson and A. Martin for advice and facilities. The Central Electricity Generating Board provided financial support for C.R.

Seed germination in response to diurnal fluctuations of temperature

DIURNAL fluctuations in temperature may initiate or accelerate germination in certain flowering plants¹⁻⁶, and the effectiveness of the stimulus varies according to the amplitude of fluctuation⁷ and the presence or absence of light⁸. Attempts^{3,6} to assess the adaptive significance of the phenomenon, however, have been limited by the scarcity of data for species of contrasted ecology. We report here an investigation of germination responses to fluctuating temperatures, conducted on seeds of herbaceous species collected from native populations near Sheffield. The results suggest that requirements for diurnal fluctuations in

temperature are characteristic of the germination of species from particular types of habitat and provide mechanisms which cause seeds to germinate at times and in places favourable for seedling establishment.

Species were screened for the capacity to respond to fluctuating temperatures in the light in two stages. First, germination was compared in two incubators. One consisted of a growth room with a diurnal fluctuation of 5 °C (20 °C day, 15 °C night) and the other was a thermogradient bar⁹ providing 'constant' temperatures (maximum diurnal fluctuation 1 °C) for 30 batches of seeds distributed at regular intervals across the range 5-40 °C. This procedure revealed a large number of species which germinated to a high percentage in fluctuating temperatures but which remained partially or totally dormant in constant conditions. Such species included several marsh plants, in some of which germination on the thermogradient bar was restricted to exceptionally high (>25 °C) temperatures.

In the second stage of screening, germination of each of these species was examined in a new incubator⁷ which provides diurnal temperature fluctuations over a selected range of amplitudes. The results described here refer to experiments in which batches, each of 30 seeds, experienced diurnal fluctuations over the amplitude range 0-12 °C. Details of the methods are given in the legend of Table 1. Each fluctuation was applied in the form of a depression

Table 1 Species in which germination in the light is promoted by fluctuating temperatures

Species	Fluctuating temperature requirement (°C)
<i>Agropyron repens</i> *	4.0
<i>Atriplex hastata</i>	6.5
<i>Bidens tripartita</i> *	4.0
<i>Cardamine pratensis</i>	7.0
<i>Carex otrubae</i>	1.0
<i>Chenopodium rubrum</i>	7.0
<i>Filipendula ulmaria</i>	1.5
<i>Gnaphalium uliginosum</i> *	5.0
<i>Juncus effusus</i>	1.5
<i>Lycopus europaeus</i> *	8.0
<i>Mentha arvensis</i> †	4.5
<i>Phalaris arundinacea</i>	1.0
<i>Polygonum persicaria</i>	8.0
<i>Ranunculus repens</i> ‡	1.0
<i>Rorippa islandica</i> *	9.0
<i>Rumex obtusifolius</i>	2.0
<i>Rumex sanguineus</i> *	2.5
<i>Sieglingia decumbens</i> *	1.0
<i>Sonchus arvensis</i>	7.5
<i>Tripleurospermum maritimum</i>	1.5
<i>Typha latifolia</i>	1.0
<i>Urtica dioica</i>	5.5

The figures indicate the amplitude of fluctuation required to attain 50% of the maximum germination recorded in the experimental conditions. Germinated seeds were counted and removed daily. Diurnal fluctuations were maintained throughout each experiment, which was terminated when germination ceased. Light intensity during the light period was 1,846 $\mu\text{W cm}^{-2}$. Before the test all seed was stored dry at 5 °C except for the following.

*20 °C dry storage.

†2 °C wet storage.

‡20 °C wet storage.

Further studies have indicated that requirements for fluctuating temperatures in certain of these species may decline gradually during extended laboratory storage.

below a base temperature of 22 °C extending for 6 in every 24 h and coinciding with a dark period. Such downward fluctuations were preferred so that no regime should impinge on the high temperatures known to initiate germination in certain of the species. Thus any responses could be attributed to the fluctuation itself rather than to experience of particular absolute temperatures.

In Table 2, the 292 species screened are classified arbitrarily into five ecologically defined groups, for each of which the proportion of species responding to fluctuating

temperatures in the light has been calculated. Some of the species stimulated by fluctuating temperatures are identified in Table 1, which also includes the amplitude required to achieve 50% of the maximum germination recorded in the experimental conditions. A high incidence of responses to fluctuating temperatures is apparent in species of marshes, bogs, streambanks and other wetland habitats. The significance of this correlation is strengthened by the fact that several ruderal species in which germination was found to depend on fluctuating temperatures, such as *Chenopodium rubrum*, *Polygonum persicaria* and *Polygonum lapathifolium*, are particularly common in areas of arable fields subject to seasonal waterlogging, and frequently colonise the mud adjacent to lakes, ponds, ditches and reservoirs¹⁰.

Further investigations with modified incubators were conducted to examine the response of seeds to diurnal temperature fluctuations in light and in darkness. Specimen results are shown in Fig. 1. In some marsh plants and ruderals darkness increased considerably the amplitude of fluctuation required to initiate germination. For many species which in light germinated rapidly and to a high percentage in constant temperatures, a large proportion of the seeds required large (>4 °C) fluctuations to germinate in darkness. This category included species from grassland, heathland and a wide range of vegetation types.

Table 2 Comparison of frequency of occurrence of requirements for fluctuating temperature for germination in the light

Habitat	No. of species examined	% Stimulated by fluctuating temperatures
Wetland	68	43
Disturbed ground	61	18
Grassland	100	2
Woodland	20	5
Remainder	43	0

Further experiments are necessary to estimate how far these results from local seed collections are representative of each species. Already, however, responses in two ecologically distinct groups are evident. The first (group 1) consists of species (mainly marsh plants) which require fluctuating temperatures for germination in the light. The second (group 2), including plants from a wide range of habitats, consists of species in which the response to fluctuating temperatures occurs only in conditions of continuous darkness or is greater in darkness than in the light. We suggest that in the two groups responses to temperature fluctuations are initiated by different environmental cues.

We consider first group 1. In temperate regions, seedling establishment in many marshland species is restricted to late spring when the water table recedes, causing bare soil to be exposed and its surface horizons to become aerobic. We suggest that fluctuating temperature requirements delay germination until such time in the spring that the declining water content of the soil causes the seed to be no longer insulated against the increasing daily radiation load.

The necessity of bare soil for seedling establishment is not confined to ruderal species. Ecologists¹¹⁻¹⁴ have noted that seedlings of many group 2 species establish successfully only in gaps in the canopy of leaves and litter. From studies of the seed content of soils¹⁵⁻²⁰ and our own measurements it is apparent that buried seeds of many herbs persist in large numbers beneath closed canopies. Such species include all those which in Fig. 1 display a requirement for fluctuating temperatures in darkness. We suggest therefore that germination is initiated in gaps in vegetation by two processes: (1) unearthing of buried seeds and triggering of germination by exposure to light and (2) germination of buried seeds *in situ*, caused

by large diurnal temperature fluctuations resulting from removal of the insulating effect of foliage and litter. The results of a temperature monitoring experiment in a grass sward (Fig. 2) confirmed that at a soil depth of 1 cm, beneath a closed canopy, diurnal fluctuations in temperature exceeded 4 °C only in exceptionally hot dry conditions, whereas, in neighbouring gaps, amplitudes greater than 10 °C were frequent.

Fig. 1 Germination responses to various amplitudes of diurnal fluctuations of temperature in light (○) and in continuous darkness (●) in nine herbaceous plants. Details of the experimental procedure are provided in the legend of Table 1. The erratic course of the 'curves' for certain species, for example, *A. repens*, probably reflects the heterogeneity of responses within the seed populations studied. In any sample of such seed there exists a mixture of phenotypes differing in response to temperature fluctuations. Such variability could be eliminated only by the use of very large numbers of seeds in the experiments. The results for *A. repens* and *P. pratensis* suggest that even when exposed to large fluctuations of temperature, a proportion of the seeds was inhibited by the light treatment. This suggests a mechanism whereby germination of seeds of these species may be delayed until after burial in the soil. a, *A. repens*; b, *D. caespitosa*; c, *H. lanatus*; d, *P. annua*; e, *P. pratensis*; f, *P. trivialis*; g, *R. obtusifolius*; h, *S. media*; i, *L. perenne*.

Control of arable weeds is complicated by the erratic germination patterns exhibited by certain species. It seems likely that one reason for the low predictability of germination in species such as dock (*Rumex obtusifolius*), couch grass (*Agropyron repens*) and chickweed (*Stellaria media*) is the heterogeneity of their seeds with respect to the amplitude of fluctuation required to induce germination in darkness (Fig. 1). In field conditions such variability is compounded by the fact that seeds are distributed throughout the soil and their exposure to temperature fluctuations will be modified by variations in incident radiation, vegetation canopy and soil moisture content.

Responses of buried seeds to fluctuating temperatures

Fig. 2 Comparison of the amplitudes of diurnal fluctuations of soil temperature beneath an established sward (●) and in an artificially created gap of 20-cm diameter (○). Measurements were made at a depth of 1 cm. Recording was carried out during the period 27 August to 18 September 1976. Each point refers to the difference between the minimum and maximum temperatures on the day concerned.

are also relevant to the 'deterioration' of pastures, characterised by a decline of the sown species (usually *Lolium perenne*) and an incursion by native grasses. Figure 1 shows that in native sward-invading species such as *Poa annua*, *P. trivialis*, *P. pratensis*, *Holcus lanatus* and *Deschampsia caespitosa*, a proportion of the seeds require large temperature fluctuations for germination in darkness. It is not surprising therefore that these species occur in the reservoir of buried seeds in pastures¹⁶ and exploit gaps in the canopy arising from damage to the vegetation. The decline of *L. perenne* may be related in part to the fact that it is insensitive to diurnal temperature fluctuations and is not incorporated into the buried seed flora.

Energy requirement for symbiotic nitrogen fixation

COMPARING the energy required by legumes for symbiotic nitrogen fixation with that of assimilation of nitrate, Gibson¹ concluded the costs to be about the same. About 15% of net photosynthetic production by the plant may be used in meeting its nitrogen requirements. If energy for the fixation of nitrogen symbiotically and that for the assimilation of NH_4^+ or NO_3^- from the soil solution are both provided by the chemical products of photosynthesis, then the CO_2 respired in supplying that energy must contribute to the total efflux of CO_2 from the plant in the dark. McCree² and Thornley³ have discussed methods of partitioning the dark CO_2 efflux into a growth (synthesis) and a maintenance component. Both nitrogen fixation and nitrogen assimilation can be expected to contribute to the CO_2 flux associated with synthesis. If Gibson is correct, nodulated plants using only symbiotically fixed nitrogen should have the same growth coefficient as non-nodulated plants supplied with exogenous mineral nitrogen when grown in the same conditions. I have examined this hypothesis using a modification of the method used by McCree with *Trifolium subterraneum* L. cultivar Woonenellup as test material.

Plants were grown at a density of 2,000 m^{-2} in square, 3-l plastic pots. The rooting medium was a fritted clay of excellent water holding capacity, low bulk density (450 kg m^{-3}) and with no measurable capacity to absorb or evolve CO_2 . Plants in one group of pots (A) were inoculated with *Rhizobium* and watered daily with a nutrient solution free of mineral nitrogen. The other group (B) was not inoculated and was watered with the same nutrient solution but with 7.5 mM NO_3^- partially replacing SO_4^{2-} . Pots were housed in a growth cabinet set at $20 \pm 0.5^\circ\text{C}$ and plants were exposed to a photosynthetic photon flux density of 500 $\mu\text{E s}^{-1} \text{m}^{-2}$ for 12 h each day. Plants subjected to the two treatments grew equally vigorously. After a full canopy had developed, the CO_2 exchange rates were measured in an assimilation chamber (open system) at 20°C and the same light flux density as the growth cabinet. CO_2 flux into and out of the whole pot was measured continuously and the total daytime influx (D) and night efflux (N) were obtained by integration. This was done for three successive 24 h periods, each pot always reaching a steady state of near constant D and N over the second and third periods. At the beginning of the fourth day the light was turned off, the plants remaining in darkness for a further 36 h. The rate of CO_2 efflux declined rapidly over the first 4 h of extended night, reaching a new, steady, low rate at the beginning of the next day: a new total 12-h efflux (N_a) was calculated from this reduced value. N_a was always about half N.

The method of estimating the growth coefficient k in the equation

$$N = kD + (1+k)cW \quad (1)$$

will be described more fully elsewhere. It is assumed^{2,4} that N_a represents the maintenance flux and is equal to cW where W is the total plant dry weight in CO_2 equivalents, and c the maintenance coefficient (mg CO_2 per g CO_2 per 12 h). The growth coefficient k represents the fraction of the net CO_2 uptake in the light (D) that is associated with the synthesis of new dry matter (g CO_2 per g CO_2) over a 12-h period.

$$k = (N - N_a)/(D + N_a) \quad (2)$$

Values of k and c averaged over six replicates were:

	k	c
A (nodulated)	0.189 ± 0.017	11.9 ± 2.0
B (non-nodulated)	0.137 ± 0.010	13.2 ± 1.8

The two values of k are highly significantly different in a t test: those of c do not differ. A value of $k = 0.144$ has been obtained for non-nodulated plants grown elsewhere in the same conditions.

Assuming the dark CO_2 efflux (that is, N) to be the same during the 12-h day as during the 12-h night, these results show that plants fixing nitrogen symbiotically from the air used 37.8% (that is 2 k) of the net daily CO_2 uptake for synthesis of new material in 24 h. Those assimilating mineral nitrogen from the soil solution used 27.4% in 24 h. Nodulated plants averaged 3.9% nitrogen, the non-nodulated 4.5%, these values being each a weighted mean for the whole plant. Nodulated plants used 810 mg of CO_2 for the synthesis of 1 g of dry weight of plant material whereas for non-nodulated the figure was 510 mg. The latter is slightly higher than the value of 494 mg calculated from data of Penning de Vries⁵ for a proximate composition of 1 g of clover biomass as protein, 0.24; carbohydrate 0.61; lipid 0.07; minerals 0.08. Calculation of the conversion coefficient (Y_G)³ by the equation:

$$Y_G = (D - N) / [(D - N) + 2(N - N_a)] \quad (3)$$

shows nodulated plants to have the value of 0.64 ± 0.14 and non-nodulated plants the value 0.72 ± 0.14 , the latter being very close to the expected value of 0.74.

I conclude from use of the method of CO_2 exchange described here that the energy requirement for symbiotic nitrogen fixation by subterranean clover is substantially greater than that required for the assimilation of mineral nitrogen from the soil.

Krameria, free fatty acids and oil-collecting bees

VOGEL'S report^{1,2} of the production of glycerides rather than nectar as rewards gathered by bees described an association involving several genera of insects and numerous plant families. We report here that members of the *Krameriaceae* produce floral lips more unusual than those described by Vogel². Our data also provide evidence that the oils of *Krameria* are collected by bees of only one genus, *Centris* (Anthophoridae), and used, mixed with pollen, as larval food.

The *Krameriaceae* is a monotypic family of about 17 species native to the New World arid and semi-arid regions from Kansas, USA to northern Argentina and Chile. The flowers of all species have five (or four) rather showy sepals (Fig. 1a, s) in a zygomorphic arrangement reminiscent of a caesalpinaceous legume flower. The true petals are dimorphic. Three (or two) of the petals are small, but petaloid, often fused at the base, and form a 'flag' above the ovary (Fig. 1a, p). The remaining two petals are highly modified into fleshy secretory glands, one on either side of the ovary (Fig. 1a, g). Two externally distinctive kinds of glands occur in two species groups within the family. One type (Fig. 1b) has bulbous swellings over the densely secreting areas of the lip and upper portion of the gland. The second type (Fig. 1c) secretes oil over the entire pebbled outer surface. Glands of both types produce the oils through a row of elongate epidermal cells (Fig. 1d). The oils collect under the cuticle, which, separates from the epidermal cells, forming lipid-filled 'blisters'.

Fig. 1 A *Krameria* flower, oil-producing glands and scraping devices of oil-collecting *Centris*. a, Flower of *K. revoluta*: a, anthers; p, petals; s, sepals; g, gland ($\times 4$). b, Gland of *K. revoluta*, freeze dried, photographed under scanning electron microscopy, (SEM) ($\times 14$). c, Gland of *K. grayi*, critical point dried, photographed under SEM. Where the cuticle has been scraped away, the epidermal secretory cells are visible ($\times 14$). d, Cross section of the edge of a gland of *K. revoluta* showing the secretory epidermal cells and the separated cuticle, light microscopy ($\times 180$). e, Left front leg terminal segment of a female *Centris* (*Paracentris*) *aterrima*, an oil-collecting visitor of *K. revoluta*, under SEM ($\times 18$). f, Basitarsal scraper of the leg in (e) showing the opposing rows of setae, under SEM ($\times 55$).

None of the species in the 49 genera in six plant families³ known or suspected to produce floral oils as rewards secretes nectar. In most of these taxa lipids are secreted by trichomes, but members of *Sigmatostalix* and *Oncidium* (Orchidaceae) and all the oil-producing Malpighiaceae have epidermal secreting cells similar to those of *Krameria*.

The only detailed chemical investigations of floral oils have been carried out by Vogel and collaborators² on trichome exudates of *Calceolaria pavonii*. They identified the major component of the crude exudate as a diglyceride of acetic acid and β -acetoxypalmitic acid.

We have analysed the floral lipids of several species of *Krameria* using a combination of thin-layer and gas chromatography, infrared spectroscopy, nuclear magnetic resonance (NMR) and mass spectroscopy. The crude oil eluted from glands reached 0.91 mg per gland. The extracts seemed to be quite pure and similar in all species sampled. Spectral data and thin-layer chromatography after saponification revealed no traces of glycerol and indicated that the major components were free fatty acids. Infrared and NMR spectra showed that the fatty acids were saturated and had an acetate moiety in the β position. Analyses of the methyl esters using gas chromatography indicated chain lengths between C16 and C20. Free fatty acids are rare in plants; as far as we can determine, β -acetate-substituted free fatty acids have not been reported before.

With two exceptions⁴, all bees presumed to collect floral oils belong to seven New World genera of the Anthophoridae. Our data (Table 1) indicate that only female bees of the genus *Centris* visit *Krameria* for oil collection. The basitarsi of the fore and midlegs of almost all oil-collecting female bees have modifications which facilitate the collection of oils. The size, shape, fine structure and orientation of the oil-collecting scrapers show considerable interspecific and intraspecific variation related in part to the type of oil-producing flower visited (that is those with epidermal cell glands compared with trichomes). All female *Centris* known to visit *Krameria* have a forebasitarsal scraping device (Fig. 1e) consisting of an inner apical comb

of flattened setae with a short opposing row of giant spatulate setae (Fig. 1f). There is also a less elaborate row of flattened setae on the midbasitarsi.

Our field observations of *Centris* females show that their oil-foraging behaviour is quite stereotyped. When approaching a *Krameria* flower, the female orients herself with the supra-ovarian petals and alights, straddling the stamens and stigma. She then grasps the base of these petals with her mandibles and rapidly rubs the scrapers on the forelegs over the glands, rupturing the blisters and accumulating the oil in the hollows of the scrapers. If manipulating oil glands, a female normally spends 2–5 s per flower, but she often approaches and rejects 30 or more flowers in succession before alighting. After accumulating oil from several flowers, she transfers it, while hovering or perched on a twig, to the scopal hairs of the hind legs. The oils can be held alone by capillary action or mixed with pollen for transport to the nest.

The oils seem to be used solely as part of the larval nest provisions. Like most members of the Anthophoridae, members of the genus *Centris* are solitary bees with each female building and provisioning her own nest cells^{3,4}. Each urn-shaped larval cell is lined with a wax-like substance and half filled with a mixture of semifluid pollen and oil, on top of which the egg is laid. Our analyses of the contents of a complete nest cell of *C. trigonoides* from Pochutla, Mexico, showed no nectar (no appreciable sugar) and large quantities of lipids mixed with pollen.

Most species of *Centris* are catholic in their choice of pollen hosts, but they do not specifically collect *Krameria* pollen for larval provision. Nevertheless, they are clearly the primary cross-pollination agents for all *Krameria* species studied. The anthers of *Krameria* flowers (Fig. 1a, a) are clustered around the slightly longer style. When the bee alights, her body first contacts the stigma and then the masses of pollen extruding from the terminal anther pores. Some of this pollen is deposited on the underside of her body (usually on the hairs of the ventral portion of the thorax, the basal portions of the mid and hind legs or on a medial tuft of hairs on the second abdominal sternite) from which it can easily be transferred to the stigma of the next flower visited. The high floral constancy observed among all oil-foraging *Centris* presumably contributes to their efficiency as pollinators. *Krameria* species which we have tested seem to be self-incompatible and require cross-pollination.

The utilisation of a diet very rich in lipids by the larvae of a group of insects generally considered to depend on nectar and pollen (a high carbohydrate, low lipid diet^{5,6}) underscores the ignorance of the nutritional requirements and metabolic capabilities of the most important single group of angiosperm pollinators, the bees. Studies such as ours on oil-producing plants and their pollinators and the chemical nature of the oils may thus reveal not only novel

kinds of lipids but new hymenopteran metabolic pathways as well.

Mating advantage of rare males in models of sexual selection

MODELS of sexual selection in polygynous species of animals have been derived on the assumption that some females have preferences to mate with males with particular genotypes^{1–3}. The mating advantage gained by the males is always frequency-dependent because the preferred males take part in the same number of preferential matings when they are rare as when they are common; individually therefore, they mate more often when they are rare. Frequency-dependent sexual selection has been demonstrated in many experiments with *Drosophila*: rare males take part in a higher proportion of matings than their frequency as available mates^{4–12}. Ehrman and Spiess¹⁰ explained this phenomenon by frequency-dependence either in female preference or in male courtship. This explanation, which is difficult to interpret in behavioural terms, may not be necessary, however, because constant female preferences would entail frequency-dependent selection among the males. I show here that a simple model of constant preferences for particular phenotypes or genotypes is sufficient to explain a large body of data on frequency-dependent sexual selection in *Drosophila*.

In models analysed previously^{1–3}, some females had mating preferences either for particular genotypes or for a phenotype determined by a dominant allele; other females mated at random. These possibilities can be combined in a model that allows for any degree of dominance as well as separate

Table 1 Fitting data of Spiess and Spiess to the model with constant mating preferences

(a) Matings with karyotypes homozygous for inversions AR and PP in *Drosophila pseudoobscura*^a

Before fitting the model $\chi^2 = 67.105$
 Maximum likelihood estimates: preference for AR, $\alpha = 0.138$
 preference for PP, $\theta = 0.021$

Ratio among males		Observed nos of matings of males		Expected nos of matings of males		Contribution to χ^2 after fitting
AR	PP	AR	PP	AR	PP	
2	18	51	214	58.856	206.144	1.348
4	16	63	135	60.627	137.373	0.134
6	14	38	60	38.249	59.751	0.003
8	12	56	43	46.965	52.035	3.307
10	10	49	37	48.031	37.969	0.044
12	8	69	37	68.115	37.885	0.032
14	6	78	19	70.489	26.511	2.928
16	4	182	41	180.807	42.193	0.042
18	2	292	40	297.104	34.896	0.834

After fitting the model $\chi^2 = 8.672$
 This value of χ^2 for 7 degrees of freedom shows there is no residual heterogeneity after the fitting of the model, the two parameters contributing $\chi^2 = 58.433$ to the overall χ^2 .

(b) Matings with strains Humboldt (Hu) and white wolf (WW) in *Drosophila persimilis*^a

Before fitting the model $\chi^2 = 101.707$
 Maximum likelihood estimates: preference for Hu $\alpha = 0.166$
 preference for WW $\theta = 0.156$

Ratio among males		Observed nos of matings of males		Expected nos of matings of males		Contribution to χ^2 after fitting
Hu	WW	Hu	WW	Hu	WW	
2	18	53	194	57.656	189.344	0.491
4	16	25	34	17.776	41.224	4.201
6	14	17	28	16.612	28.388	0.014
8	12	18	17	15.296	19.704	0.849
10	10	25	25	25.245	24.755	0.005
12	8	15	20	20.047	14.953	2.974
14	6	24	13	23.704	13.296	0.010
16	4	32	23	38.968	16.032	4.275
18	2	175	43	169.251	48.749	0.873

After fitting the model $\chi^2 = 13.692$
 This value of χ^2 shows no residual heterogeneity, the two parameters contributing $\chi^2 = 88.015$ to the overall χ^2 .

In the data of this table the matings of the two male genotypes are recorded in relation to the genotypes of females which were in a constant ratio of 50% while the males' frequencies were varied. Although PP and WW females mated less frequently than AR and Hu females, there is no evidence for assortative mating preferences in the two experiments and no heterogeneity in the relative frequencies of the matings of the males with the two female genotypes. In this table, therefore, the numbers of matings with the two genotypes of females have been added together.

preferences for each genotype. The preferences can be defined as follows:

genotypes	AA	AA'	A'A'
frequencies of genotype in population	u	v	w
proportions of females preferring each genotype separately	α'	β'	γ'
proportions of females preferring 'A' phenotypes	$au/(u+v) \quad av/(u+v) \quad -$		

It can then be shown¹³ that in the following generation the genotypic frequencies become

$$\begin{aligned} u' &= \phi p + \alpha p^2/(1-w) + p^2(1-\alpha-\theta) \\ v' &= \phi q + (\theta-\phi)p + \alpha p(2q-w)/(1-w) + 2pq(1-\alpha-\theta) \\ w' &= (\theta-\phi)q + \alpha q(q-w)/(1-w) + q^2(1-\alpha-\theta) \end{aligned}$$

where $p = u + \frac{1}{2}v$ and $q = w + \frac{1}{2}v$ are the gene frequencies of A and A'; and $\phi = \alpha' + \frac{1}{2}\beta'$, $\theta = \alpha' + \beta' + \gamma'$. Thus $\alpha + \theta$ is the total proportion of all females who mate preferentially; the remaining proportion $1 - \alpha - \theta$ mate at random. A stable polymorphic equilibrium is established at a gene frequency of A'

$$q_* = \frac{-\phi + \sqrt{(\phi^2 + 4(\theta-\phi)(\alpha+\theta))}}{2(\alpha+\theta)} \quad (1)$$

For a change of gene frequency from q_0 to q_n over a period of n generations, approximately

$$\left\{ \frac{q_n - q_*}{q_0 - q_*} \right\}^{(q_* + 1)} \left\{ \frac{q_n + q_* + a}{q_0 + q_* + a} \right\}^{(q_* + a - 1)} = \exp[-n(q_* + a)(\alpha + \theta)] \quad (2)$$

where $a = \phi/(\alpha + \theta)$.

Two cases are likely to apply to sexual selection in natural populations. When $\phi = \theta = \alpha'$ and $\beta' = \gamma' = 0$, A is at an unconditional advantage and spreads through the population to complete fixation. Among the females, a proportion α are more responsive to both AA and AA' males and a proportion ϕ are more responsive only to AA males. Thus in its effect on mating preference A is being selected as a semi-dominant or semi-recessive allele depending on the magnitudes of ϕ and α . In addition, some females may prefer A'A' males. Then $\phi = \alpha'$ and $\theta = \alpha' + \gamma'$ where γ' is the proportion of females preferring A'A' males. This produces a stable polymorphism at an equilibrium frequency given by equation (1). When A is completely dominant $\phi = \alpha' = 0$ and

$$q_* = \sqrt{(\theta/(\alpha + \theta))} \quad (3)$$

In this case $a = 0$ and the change in gene frequency over a period of n generations becomes

$$\begin{aligned} \left\{ \frac{q_n - q_*}{q_0 - q_*} \right\}^{(q_* + 1)} \left\{ \frac{q_n + q_*}{q_0 + q_*} \right\}^{(q_* - 1)} \\ = \exp[-nq_*(\alpha + \theta)] \quad (4) \end{aligned}$$

These models explain the establishment of stable polymorphisms in population cages of *Drosophila*. Equation (4) could be used to estimate the values of q_* and the total preference, $\alpha + \theta$. Combined with direct estimates of α and θ from observations of the numbers of the different matings, this would provide an independent test of the model.

If observations have been made of the numbers of matings for a range of different frequencies, the estimates of α and θ

can also be tested for heterogeneity against the null hypothesis that the proportions of females with preferences, α and θ , remain constant and determine the numbers of matings at each different frequency of the male genotypes. This test can be applied to Ehrman's and Spiess' data of number of matings of males at varying frequencies. Males of two different genotypes were used in the experiments. Females were introduced into the mating chamber containing the males and the genotype of the mated male was recorded. According to the model, the expectations are as follows:

genotypes	AA	BB
frequencies of genotypes of males	u	v
proportions of females preferring each genotype	α	θ
proportions of matings with each genotype	$\alpha + u(1 - \alpha - \theta) \quad \theta + v(1 - \alpha - \theta)$	

Suppose, in the i th experiment a_i and b_i are the numbers of matings observed with A and B males at frequencies u_i and $v_i = 1 - u_i$, then the log likelihood for all of k experiments is

$$\log_e L = \sum_{i=1}^k a_i \log[\alpha + u_i(1 - \alpha - \theta)] + \sum_{i=1}^k b_i \log[\theta + v_i(1 - \alpha - \theta)]$$

Maximum likelihood estimates of α and θ are then obtained as the values which maximise $\log_e L$. I have calculated these estimates by trial and error, starting with arbitrarily chosen values of α and θ and introducing random perturbations in the initial values until higher values of $\log_e L$ are found. By making the maximum size of the random perturbations smaller and smaller, the maximum of the log likelihood surface is reached by a random walk of successively smaller steps.

In Ehrman's experiments^{5, 6, 11}, the frequency of the female genotypes varied with the frequency of the male genotypes. Spiess^{8, 9}, however, kept the frequencies constant among the individuals who were being offered the choice of mates. Choice was generally exercised only by the females, the males mating at random when offered a choice of female genotypes. In his experiments on female choice, Spiess varied the frequencies of the male genotypes between experiments while maintaining the frequencies of the genotypes at 50% in the females. Thus, if choice varied according to genotype, this could not be a cause of the frequency-dependent advantage gained by the males in Spiess' experiments. Table 1 shows the data Spiess obtained and the fit of the model. The model provides a satisfactory fit with no residual heterogeneity after the expected numbers of matings have been calculated using the maximum likelihood estimates of α and θ from the total data of each of the experiments.

Table 2 shows the results of fitting Ehrman's data⁵ on the effect of frequency on the matings of males homozygous for the karyotypes CH and AR in *Drosophila pseudoobscura*. In these

Table 2 Fitting data of Ehrman⁵ on matings with karyotypes homozygous for inversions CH and AR in *Drosophila pseudoobscura* to the model with constant mating preferences

(a) Matings in a line that had been selected for positive geotaxis in previous generations						
All matings			Early matings			
Ratio among males	Observed nos of matings	Contribution to χ^2 after fitting	Observed nos of matings		Contribution to χ^2 after fitting	
CH	AR		CH	AR		
18	2	3.105	31	25	1.816	
16	4	0.140	36	24	0.025	
14	6	2.000	37	25	0.809	
12	8	2.662	21	33	2.198	
10	10	0.887	23	30	0.007	
8	12	9.645	31	23	7.731	
6	14	3.452	26	28	4.857	
4	16	0.070	14	45	0.778	
2	18	8.499	7	48	3.791	
Preference for CH		$\alpha = 0.217$			$\alpha = 0.189$	
Preference for AR		$\theta = 0.328$			$\theta = 0.310$	
Deviation from $\alpha = \theta = 0$		$\chi^2_2 = 213.591$			$\chi^2_2 = 98.014$	
Residual heterogeneity		$\chi^2_7 = 30.460$			$\chi^2_7 = 22.013$	
There is significant residual heterogeneity for the matings with male ratios 8:12 and 2:18. There are significantly too many matings of the less common males at the ratio 8:12 and too few matings of the less common males at the ratio 2:18. Otherwise, the fit of the model is very good with no consistent deviations from the model.						

(b) Matings in a line that had been selected for negative geotaxis in previous generations						
All matings			Early matings			
Ratio among males	Observed nos of matings	Contribution to χ^2 after fitting	Observed nos of matings		Contribution to χ^2 after fitting	
CH	AR		CH	AR		
18	2	3.089	45	9	2.728	
16	4	0.208	39	20	0.062	
14	6	0.039	36	20	0.143	
12	8	12.461	24	36	6.268	
10	10	1.122	26	32	0.683	
8	12	1.044	28	35	0.000	
6	14	0.720	21	35	0.033	
4	16	3.356	24	32	2.517	
2	18	0.005	16	43	0.000	
Preference for CH		$\alpha = 0.243$			$\alpha = 0.213$	
Preference for AR		$\theta = 0.292$			$\theta = 0.208$	
Deviation from $\alpha = \theta = 0$		$\chi^2_2 = 148.036$			$\chi^2_2 = 48.361$	
Residual heterogeneity		$\chi^2_7 = 22.044$			$\chi^2_7 = 12.435$	
There is still some residual heterogeneity among all matings after the fit of the model. This heterogeneity is determined by the high frequency of matings of the less common males at the ratio of 12:8.						

experiments, data at some frequencies show significant deviations from expectation after the fitting of the model: the ratios of 8:12 in the positively selected line and 12:8 in the negatively selected line show a great excess of matings of the less common males. No simple model would resolve these anomalies because at these ratios the mating advantage shows no particular relationship, frequency-dependent or not, with the mating advantages at the other ratios: there are no consistent deviations from the model. If preferences were genetically determined, chance would produce sampling variation in the proportions of females expressing a preference. If α and θ do vary between experiments, then the variance in the observed numbers of matings will be greater than the binomial variance. This will therefore inflate the values of χ^2 which have been calculated on the assumption of binomial variation. I consider this to be the most likely cause of the statistically significant heterogeneity in Ehrman's data. A model of the expected variance in α and θ would have to be constructed in order to calculate a corrected value of χ^2 .

Ehrman's experiment¹¹ on frequency-dependent mating for two recessive alleles *or* (orange) and *pr* (purple) also shows residual heterogeneity that is just statistically significant, and also without any systematic deviations from the model. In this experiment population cages were started at ratios of 80 *or*: 20 *pr* and 20 *or*: 80 *pr* and continued for 10 generations. In each generation the actual matings of 100 pairs were observed. It is to be expected that the mating preferences would vary between generations mainly as a result of sampling genetic drift. The variance in the observed numbers of matings must be greater than the binomial and χ^2 will therefore be inflated. Fitting the model to the data gives $\alpha = 0.244$ for the preference for *or* and $\theta = 0.259$ for the preference for *pr*. Before fitting the parameters, $\chi^2_{20} = 64.132$; and after fitting, $\chi^2_{18} = 30.823$ ($0.05 > P > 0.02$).

Ehrman⁷ tried to show "how a *Drosophila* female knows which males are rare". On my theory, the females do not have to carry out the difficult task of discriminating between rare and common males: constant mating preferences are sufficient to explain the observed frequency-dependence. In some of Ehrman's experiments, the mating advantage disappeared if the rare males in the mating chamber were the common males in an adjacent chamber from which air was passed into the mating chamber. This was interpreted to mean that olfactory stimuli from the adjacent chamber where the males were common prevented the discrimination of rare males in the mating chamber. The results, however, were "inconsistent and ambiguous" in some of these experiments. Sampling variation in the proportions of females expressing preferences might be the cause of both this inconsistency and the residual heterogeneity after fitting the data of some of Ehrman's experiments to my model.

O'Donald¹³ discussed the possible behavioural mechanisms which might give rise to mating preference. Some females may have a lower threshold of response to some male genotypes and would require less stimulation to mate with them. They would thus mate more readily with the preferred males and more readily than the other females who mate at random. The presence of other courting males will raise the general level of stimulation so that all females are stimulated to mate more readily. A female with a lower threshold towards a particular genotype of male would then mate more readily with any male. The proportion of preferential matings would therefore decline with increasing density. The mating preference, according to this model, will be density-dependent but not frequency-dependent. The disappearance of mating choice in some of Ehrman's experiments could be the results of the increased level of stimulation provided by the extra males in the adjacent chamber. A similar result would follow if the different male genotypes determined different levels of courtship activity. A more responsive female would be sufficiently stimulated by any male and so would mate more or less at random. A less responsive female would mate more readily with one of the more active males and would therefore tend to show a preference

that decreased at higher levels of stimulation. The mating preferences could thus be determined by variation either in male courtship or in female response. Both types of behavioural mechanism would explain observations of mating choice in *Drosophila*.

Spontaneous forward mutation versus reversion frequencies for maize *Adh1* in pollen

RELIABLE quantitative data on spontaneous, specific gene mutation frequencies in higher plants and animals are few. Detergents include low natural frequencies and difficulty in obtaining in excess of 10^6 scorable organisms or gametophytes. The *alcohol dehydrogenase-1* gene (*Adh1* gene; ADH enzyme EC 1.1.1.1.), as expressed in pollen grains, is among the exceptionally suitable; much is known about the maize ADHs¹⁻³, *Adh1* function is totally dispensable in an aerobic environment and maize pollen is a trinucleate gametophyte which expresses much of its haploid genome, including *Adh1*^{4,5}. In particular, there have been two recent methodological advances. First, I am able to cytochemically stain pollen, before⁶ or after *in vitro* germination, for the presence of above 5% normal ADH activity. And second, ADH⁻ pollen grains survive allyl alcohol (C=C-C-OH) vapour concentrations which kill ADH⁺ grains^{6,7}; this selection scheme was developed for yeast by Megnet⁸. My genetic resolution is approximately one mutant (*Adh1*⁺→ADH⁻) per 10^7 chemically selected, viable gametophytes, and one (phenotypic) revertant (*Adh1*⁻→ADH⁺) per 10^8 unselected gametophytes. In this note, I compare spontaneous forward mutant frequency with previously published⁹ revertant frequencies for one naturally occurring and six ethyl methanesulphonate-induced *Adh1*-deficient (*Adh1*⁻) alleles.

About 2% of normal, *Adh1*⁺ pollen grains stain poorly in the ADH-specific reagents, a condition which almost always denotes inviability. For that reason, it was necessary to count ADH⁻ gametophytes among viable pollen rather than among total pollen. My methods were developed by using *Adh1*⁺/*Adh1*⁻ (*Adh1*- γ 25; CRM⁻; unpublished) heterozygotic plants segregating 1:1 for blue, opaque:yellow, translucent pollen. Pollen was collected under controlled conditions, cold treated, exposed to a series of allyl alcohol vapour concentrations, germinated on a slice from 'David's Bread Loaf' medium and subsequently frozen. The ice-perforated grains were then stained for ADH activity (methods described in Fig. 1 legend). Figure 1 shows the final result for an allyl alcohol concentration which kills 99.999% ADH⁺ pollen without affecting the viability of the 50% ADH⁻ grains: none of the blue, opaque grains have pollen tubes.

Wild-type *Adh1*⁺ pollen (either *Adh1*-S or *Adh1*-F isoalleles) was collected in an isolation greenhouse and treated according to the protocol outlined above. Allyl alcohol

Fig. 1 Pollen shed from an *Adh1*⁺/*Adh1*⁻ plant after allyl alcohol treatment, *in vitro* germination, and *in situ* staining for ADH activity. Pollen was collected before 10 a.m., weighed, stored desiccated (CaSO₄) at 4 °C for 3 h and treated with 300 µM allyl alcohol for 30 min in a 500 ml sealed Mason jar. The treated pollen was brushed on to 2 mm slices from 'David's Bread Loaf' medium⁷, much modified from that of Cook and Walden¹¹, and allowed to germinate for 45 min. The slabs were frozen at -23 °C for 3 h and defrosted 30 min at 25 °C. ADH-specific stain was layered over the gametophytes three times, each for 30 min as previously described⁵. ADH⁺ gametophytes stained blue and opaque.

concentrations were chosen which allow a few ADH⁺ gametophytes to germinate. A forward mutant (*Adh1*⁺→ADH⁻) would be a yellow, translucent pollen grain with tube (allyl alcohol resistant) surrounded by blue, opaque non-germinated grains. Since pollen is naploid, ADH⁻ mutants might include modifiers. As shown in Table 1,

there were zero viable ADH⁻ grains among 4.9×10^6 viable gametophytes. The reliability of these data is supported by the following two considerations. (1) That allyl alcohol does not appreciably affect the viability of ADH⁻ pollen grains was insured by using borderline concentrations where some ADH⁺ gametophytes germinate; previous experiments⁷ indicated that the allyl alcohol concentrations I used killed no more than 20% ADH⁻ grains. (2) As a further control, I scored pollen shed from wild-type plants after the immature tassel containing the pollen mother cells was X-irradiated (last line, Table 1). Since the radiation-induced mutant frequency was rather high, these methods would have detected ADH⁻ gametophytes if they had occurred (*Adh1*⁺→ADH⁻ in mutants/viable gametophyte) at a frequency much above 2×10^{-7} .

My previous work⁵ quantified the (phenotypic) revertant frequencies (ADH⁺ revertants/unselected gametophyte) for one naturally occurring and six ethylmethane sulphonate-induced *Adh1*⁻ mutants. These mutants, recovered and characterised by Schwartz (see ref. 5) were chosen at random; two are CRM⁻ while the remaining five have lesions involving the structural gene component of the cistron. Five mutants are from the same inbred line³. A 'revertant' includes all mutants capable of changing an *Adh1*⁻ (yellow, translucent) to an ADH⁺ grain (blue; opaque): true revertants, second site revertants, unlinked suppressors; supersuppressors and overproducers are also possible for some mutants. An interesting mode of reversion would be the 'derepression' of the *Adh2* gene which is generally switched off in pollen; although possible, this explanation for high revertant frequency is not likely⁸. Reversion involving altered metabolic circuitry is not a factor since I measure *in situ* enzyme activity directly. The revertant frequencies $\pm 1 \text{ s.e.} \times 10^6$ were 1.6 ± 0.4 ; 7.3 ± 1.4 ; 2.1 ± 1.0 ; 7.2 ± 1.1 ; 10.8 ± 1.7 ; 1.2 ± 0.3 and 5.7 in ADH⁺ per gametophyte. The median revertant frequency was 5.7×10^{-6} ADH⁺ per gametophyte. This frequency is an underestimate, since 5% normal ADH activity and perhaps as

Maize	<i>wx</i>	$<7 \times 10^{-7}$	mutants/seed	16	7×10^{-6}	revertants/pollen	14	17	>10
	<i>Adh1</i>	$<2 \times 10^{-7}$	mutants/viable pollen	—	5.7×10^{-6}	revertants/pollen	7	—	>29
Mouse	<i>a, b, c, d,</i> and <i>In</i> pooled	$1.3 \times 10^{-5}\ddagger$	mutants/locus/mouse	18	$2.7 \times 10^{-6*}$	revertants/locus/mouse	5§	18	0.2

* All were either true revertants or other intragenic events.

† Of 24 X-ray induced mutants, only these four reverted at frequencies above 2×10^{-8} .

‡ Macroleisions pass through the gametes.

§ One allele for each of these five loci; only *a* and *d* gave revertants where f s below 2×10^{-6} per locus per mouse go undetected.

|| Auerbach and Kilbey¹⁹ commented: "Surprisingly, forward and reverse mutation rates at five of these loci differed only by a factor of three."

high as 30% normal ADH activity/gametophyte is scored as ADH⁻ (ref. 5). Recovery and analysis of these revertants is most important and is underway. In any case, $5.7 \times 10^{-6} / <2 \times 10^{-7}$ gives a >29-fold excess of spontaneous revertant over forward mutant frequency.

The comparison of forward mutant and revertant frequencies for specific genes is fraught with methodological pitfalls, hidden assumptions and statistics of dubious applicability. Table 2 compiles some comparative data for a few genes in a few organisms. These data comprise the totality of reliable data found—no selection was intended. Some of the more apparent considerations affecting the reliability of these data follow. Higher animals are expected to show inflated forward mutant frequencies in the absence of rigorous genetic analyses because there is no haploid (gametophytic) stage to impede the transmission of macrolesions. Ideally, a revertant frequency per gene should be based on the median frequency of several revertable alleles. Spontaneous reversion data for *Drosophila* is for 'unstable' alleles or for too few alleles (M. M. Green, personal communication; Green also notes that high reversion is expected of insertion-type mutants). Marker effects perhaps reflecting the mutagenic agent, the contribution of alternative metabolic pathways to reversion frequencies, meiotic effects, variation in modifiers of spontaneous mutagenesis, cell lineage differences between sexes, and differences in germ cell development are all known to affect mutation rates in certain cases. The fundamental nature of the cistron itself might also differ among different organisms^{9,10}. It is generally believed that forward mutant frequencies exceed median revertant frequencies, especially when suppressors are ruled out. But the data for the purple adenine mutants in *Neurospora* and five coat colour loci in mice (Table 2) do not fit this rule. Observations on red adenine mutants in yeast—the homologue of purple adenines in *Neurospora*—support the canonical view that spontaneous forward mutation exceeds median reversion frequencies (H. Roman, personal communication). The clear excess of revertant frequency over forward mutant frequency for the two cistrons studied in maize might be explained readily if almost all revertants were suppressors. However, for both *Adh1* and *wx* (Table 2), every mutant gave relatively high revertant frequencies; nonsense suppression is not likely.

The significance of our *Adh1* comparison and the few other results where spontaneous reversion exceeds forward mutation frequency cannot be assessed readily. It is clear that evolutionary and other arguments resting heavily on

the assumption that reversion frequencies are comparatively negligible should be reevaluated.

This work was supported by the US NIH and the California Agricultural Experiment Station. I thank David S. K. Cheng for expert technical assistance and Roy Sahara for nursery work.

Determinant selection is a macrophage dependent immune response gene function

IMMUNE response (Ir) genes are linked to the species histocompatibility complex and define as yet uncharacterised phenotypic products which control the immune response to thymus dependent antigens¹. Antibody formation² and antigen induced T lymphocyte proliferation³ are two examples of immune phenomena which, *in vivo* and *in vitro*, operate under Ir gene influence. To clarify their mechanism of action and cellular location, we have examined the contribution of antigen structure (amino acid sequence and conformation to Ir gene control of antigen recognition by T lymphocytes) as well as to the critical role played by the antigen presenting macrophage in expression of that control^{4–7}. We report that immune response gene control of antigen recognition operates at least in part at the level of the macrophage.

Recent studies of *in vitro* T-cell proliferation in insulin in inbred guinea pigs offered us a unique opportunity to examine, operationally, the site of Ir gene product function¹. T cells from both strain 2 and 13 guinea pigs immunised with pork insulin in complete Freund's adjuvant proliferate *in vitro* response to insulin. The determinant recognised by the strain 13 guinea pig resides in the B-chain region of the insulin molecule as evidenced by the capacity of insulin immune strain 13 but not strain 2 guinea pigs to respond to isolated oxidised B chain. When strain 2, 13 and F₁ (2×13) guinea pigs are immunised with oxidised B chain, strain 13 and F₁, but not strain 2, respond to either isolated B chain or native insulin. Genetic analysis of backcrossed and phenotypically characterised outbreds immunised to B chain showed that the relevant immune response gene defining response to the B chain determinant is linked to the strain 13 guinea pig histocompatibility complex. By contrast, the strain 2 inbred guinea pig T cell recognised insulin through a determinant present in insulin A chain. More specifically, they recognised the A chain loop and their T-cell response is sensitive to amino acid changes in position A8, A9 and A10. Insulins with total identity in this area completely cross-react in T cell proliferation and T helper cell activity. Insulins with partial or no identity in these amino acids residues show partial or no cross-reactivity respectively. In strain 13 animals, different species variants of insulin show cross-reactivity at a T-cell level independent of their A chain loop constitution. As anticipated, F₁ T cells from insulin immune guinea pigs are able to recognise either determinant.

We assessed the function of macrophages in Ir control taking advantage of the capacity of T cells from insulin immunised F₁ (2×13) guinea pigs to respond to antigen bearing parental macrophages. We reasoned as follows.

If Ir gene function operates exclusively at the level of the responding lymphocyte, both determinants should be simultaneously recognised by F₁ T cells independently of which parental macrophage (Mφ) is 'presenting' the antigen. Conversely, if the definition of which determinant is actually recognised depends on the genetic profile of the antigen presenting Mφ, then Ir gene function must also be operating at this cell level. The data that follow favour the latter assumption. Mφ from both inbred strains of guinea pig are able to 'present' pork insulin to pork insulin immune F₁ (2×13) lymphocytes (Table 1). As with PPD, a strong proliferative response is observed when pork insulin pulsed Mφ from either strain of guinea pig are added to F₁ PELs. When different species variants of intact insulin are presented to the same pork insulin immune F₁ PELs by either strain 2 or 13 Mφ, however, two different patterns of response are seen (Fig. 1). An A-chain loop pattern of cross-reactivity is observed when the antigens are presented on

Table 1 DNA synthetic responses of T cells from pork insulin immunised F₁ (2×13) guinea pigs to parental macrophages pulsed with native insulin

Macrophages pulsed with:	Macrophage genetic background	
	Strain 2	Strain 13
	³ H-TdR incorporation Δc.p.m. × 10 ⁻³	
PPD	197.45 ± 6.60	175.04 ± 29.91
Pork insulin	45.51 ± 11.34	62.42 ± 10.59

F₁ (2×13) guinea pigs were immunised with 100 μg of pork insulin in CFA, 2–3 weeks before use. Oil induced, macrophage-rich peritoneal exudate cells were pulsed with 100 μg ml⁻¹ antigen and 40 μg ml⁻¹ of mitomycin C at 37 °C for 60 min. After four washes 1.2 × 10⁶ of these cells were added to 2.4 × 10⁶ responding peritoneal exudate lymphocytes depleted of adherent cells (PELs) in 200 μl of 5% heat inactivated male guinea pig serum in RPMI-1640 plus 2.5 × 10⁻⁵ M of 2-mercaptoethanol in round microtitre plates. After 48 h of culture 1 μCi of ³H-methyl-thymidine (6.7 Ci mmol⁻¹) was added for an additional 24 h. Cells were collected on glass fibre filters with a semi-automated microharvester (Adaps) and ³H-thymidine incorporation determined by liquid scintillation spectrometry. Data are mean ± s.e.m. from four experiments. PPD, purified protein derivative of tuberculin.

Fig. 1 Different response patterns observed in F₁ (2×13) guinea pig pork immune T cells when the antigen are 'presented' by strain 2 or strain 13 macrophages. In an experimental protocol similar to that described in Table 1 pork insulin immune F₁ (2×13) T cells were challenged 'in vitro' by strain 2 and strain 13 Mφ pulsed with pork, beef and sheep insulins. When the different insulins are presented by strain 2 Mφ, there was a good proliferative response to pork insulin, an intermediate response to beef insulin and almost no response to sheep insulin. There was a substantial proliferative response to the three different insulins when presented on strain 13 Mφ (b). Beef and pork insulins share one identity in the insulin A-chain loop and pork and sheep share no amino acids identities in this area (a). The amino acid sequence of the remainder of the beef, pork and sheep insulin molecule is identical.

strain 2 Mφ. This pattern of cross-reactivity is characterised by partial cross-reactivity between pork and beef insulin (partial identity in the loop) and little cross-reactivity between pork and sheep insulin (no identities in the loop). To corroborate the above findings and to show that a specific B-chain determinant is being selected when the whole insulin molecule is presented by strain 13 Mφ, we studied the response of oxidised insulin B chain immune F₁ (2×13) PELs to parental Mφ pulsed with native insulin or isolated B chain. Only strain 13 Mφ can present native insulin to B chain immune F₁ (2×13) PELs (Table 2). Despite the capacity of strain 2 Mφ to present the same insulin to insulin

Table 2 DNA synthetic response of T cells from oxidised B chain immunised F₁ (2×13) guinea pigs to parental macrophages pulsed with native insulin and isolated B chain

Macrophages pulsed with:	Macrophage genetic background	
	Strain 2	Strain 13
	³ H-TdR incorporation Δc.p.m. × 10 ⁻³	
PPD	145.81 ± 11.32	98.01 ± 14.10
Pork insulin	0.10 ± 0.09	13.16 ± 3.09
Oxidised B chain	6.84 ± 3.74	66.90 ± 19.60

Experimental procedures were as for Table 1 except F₁ (2×13) guinea pigs were immunised with 10 μg of oxidised insulin B chain 2–3 weeks before use. Data are mean ± s.e. for five experiments.

immune F₁ T cells, they cannot initiate DNA synthesis in B-chain immune F₁ T cells. Parenthetically, a considerable proliferative response is also seen when isolated insulin B chain is presented to F₁ T cells on strain 13 Mφ but less response is seen when the same antigen is bound to strain 2 Mφ.

Such studies raise the possibility that in F₁ (2×13) animals immunised to insulin, two distinct sets of clones of T cells are generated: one that recognises the α loop antigenic determinant 'processed' by or 'presented' by the strain 2 specific cell structures in the F₁ Mφ, and one that recognises

the B-chain determinant generated by the strain 13 counterpart of the system. This hypothesis has been examined by bromodeoxyuridine (BUdR) and light elimination experiments* in F₁ guinea pigs.

Initial culture of insulin bearing parental macrophages with insulin immune F₁ T cells in the presence of BUdR and light selectively decreases responsiveness, on subsequent exposure to insulin bearing macrophages identical to those originally used to elicit cell activation (Table 3). Thus, preculture of F₁ T cells with strain 2 macrophages bearing insulin significantly depresses (65%) their response to antigen on strain 2 macrophages on subsequent cultures without comparably affecting responsiveness to insulin presented by strain 13 macrophages. Conversely, exposure of F₁ T cells to strain 13 macrophages bearing pork insulin eliminates 87% of responsiveness on repeat culture to pork insulin on strain 13 macrophages but does not affect the response of F₁ T cells to strain 2 macrophages bearing pork insulin. The clone remaining after elimination of T-cell proliferation by strain 2 macrophages pulsed with pork insulin responds equally well to strain 13 Mφ pulsed with either sheep (32,010 c.p.m.) or pork insulin (36,530 c.p.m.). Sheep insulin is identical to pork insulin except for the three amino acids of the A-chain α loop. Correspondingly, after BUdR and light elimination by strain 13 macrophages bearing insulin, the remaining cells respond only to strain 2 Mφ bearing pork but not sheep insulin.

Although immune specificity is traditionally considered a lymphocyte function*, previous observations from ours and from other laboratories indicate that the macrophage has some discriminatory function in the antigen recognition process (refs 3, 7, 9, 10, 12, 14, 15, 17).

Table 3 BUdR and light elimination of antigen specific F₁ T-cell proliferation: intramolecular determinant selection by pork insulin-bearing parental macrophages

Macrophages used in 1st culture	% Elimination of F ₁ T-cell DNA synthetic response on 2nd culture	
	Macrophage used:	
	Strain 2	Strain 13
Strain 2	65 (25-96)*	7 (0-12)
Strain 13	0	87 (70-97)

Immune PELs at 1×10^6 ml⁻¹ were cultured with 3×10^5 mitomycin C treated insulin pulsed Mφ for 48 h in 12 × 75-mm capped plastic tubes. At the end of this time $2 \mu\text{g ml}^{-1}$ of freshly prepared BUdR was added to the cultures. Twenty-four hours later, the cell pellets were exposed to light by placing the culture tubes directly on an array of three fluorescent light bulbs (Cool-Ray GE) for 90 min. After four washes of the cell pellet with Hanks BSS, the BUdR and light-treated cells were cultured a second time in microtitre plates (as described in Table 1) in the presence of added pork insulin-pulsed Mφ. Data are expressed as % inhibition of DNA synthesis remaining after BUdR and light treatment. BUdR is a thymidine analogue which, if present during the S phase of the cell cycle, is incorporated into newly synthesised DNA and cross-links DNA strands upon light activation. Treatment of activated lymphocytes with BUdR and light leads to an irreversible block in cell replication.

*Values are averages of three experiments, with range in parentheses.

Although not excluding the possibility that Ir genes also function at the T-cell level, our data suggest that macrophages have a fundamental role in selecting, in a complex antigen, the moiety(ies) to be recognised by immune T cells. Indeed these experiments are of particular relevance in view of recent studies using BUdR and light to eliminate antigen specific T cells in populations of F₁ (2 × 13) lymphoid cells from guinea pigs immune to multi-determinant antigens¹⁸. Such experiments showed that elimination of T cell responsive to antigen associated with macrophages of one parental haplotype failed to eliminate responsiveness to the same antigen on the other parental macrophage. Those data were interpreted to indicate either: (1) that cells possess dual receptors, one for antigen and a second independent receptor for H-linked surface molecules or (2) that a

'compound antigen determinant' consisting of antigen in unique association with an Ia antigen not antigen alone, is recognised by a single T-cell receptor¹⁹. An additional interpretation raised by our studies of the immune response to insulin, is that a selected amino acid sequence and/or conformation within the antigen itself is seen by the T-cell receptor. Generation or display of such antigenic determinants would thus be a function of immune response genes operating at the level of the antigen presenting cell. Two general mechanisms by which macrophages might subserve such a function may be proposed. One possibility is that immune response genes define a class of receptors or broad specificity which recognise molecular shape and thus have the unique ability to focus or orient distinct regions of the antigen for presentation to the T cell. A second possibility is that immune response gene products are or regulate the activity of families of enzymes which modify or metabolise polypeptide antigens. In this latter situation, the repertoire of Ir genes associated with a given haplotype would define restricted areas of the molecule as available for display to the T-cell receptor. Experiments to distinguish these possibilities are in progress.

Nucleoside-specific tolerance suppresses anti-nucleoside antibody forming cells

SINCE its original development by Jerne¹, the haemolytic plaque assay has increased our understanding of antibody formation to a wide variety of antigens, including proteins, lipopolysaccharides, and simple haptens². We have now developed an assay to detect plaque forming cells (PFC) making anti-nucleoside antibodies. Previously we reported the suppression of circulating antibody to DNA determinants by nucleoside-IgG conjugates^{3,4}. Here we show that BALB/c mice can be rendered tolerant in terms of both direct and indirect anti-nucleoside antibody forming cells and that the state of tolerance is nucleoside-specific at the cellular level.

Nucleosides were conjugated to BALB/c IgG2a (RPC₅) myeloma protein as tolerogen or to keyhole limpet haemocyanin (KLH) as immunogen by the procedure of Erlanger and Beiser⁵. Tolerogen preparations were (AGCT)₂₅-IgG2a and G₂₅-IgG2a and the immunogen preparation was (AGCT)₁₂₀-KLH; (the subscript numbers indicate the total molar ratio of hapten substitution on the

carrier, assuming 800,000 as the molecular weight of KLH).

To determine whether BALB/c mice immunised with 0.2 mg of AGCT-KLH in complete Freund's adjuvant intraperitoneally would produce antibody forming cells to AGCT-target sheep cells, groups of five mice were killed and assayed for direct and indirect PFC on various days after immunisation. The peak of direct anti-nucleoside PFC development occurred on days 6 and 7, and that of indirect

Fig. 1 Development of specific anti-nucleoside PFC, measured as the geometric mean ($\pm$ s.e.) PFC per spleen for groups of three non-immunised mice or five mice immunised with 0.2 mg of AGCT-KLH on day 0. Target cells were AGCT-SRBC. $\circ$, Direct and $\triangle$, indirect anti-nucleoside PFC in immunised mice. $\bullet$, Direct anti-nucleoside plaques in non-immunised mice. $\blacktriangle$, PFC to unsubstituted SRBC in immunised and non-immunised mice. The animals were 8–10 wk old BALB/c males (Jackson Laboratory). To prepare nucleoside-SRBC target cells, nucleosides were conjugated to the cells by the method of Erlanger and Beiser⁹ as modified to eliminate conditions that were damaging to the cells. A mixture of 5 mg of each nucleoside was oxidised in 1.5 ml of 0.1 M sodium periodate in 0.15 M NaHCO₃ for 20 min at room temperature; the reaction was stopped by the addition of 15 μ l of ethylene glycol. Sheep erythrocytes were washed twice with 0.15 M NaHCO₃ and 0.5 ml of packed cells were then suspended in 2.0 ml of the bicarbonate solution in a 40 ml centrifuge tube. The oxidised nucleosides were added dropwise to the cell suspension and the mixture was kept at room temperature for 15 min. 100 mg of *t*-butylamine borane (Aldrich) in 5 ml of 0.15 M NaHCO₃ was added. The suspension was kept at room temperature for 3 min and the tube was quickly filled with bicarbonate solution and centrifuged at 1,500 r.p.m. for 10 min. The modified cells were washed twice more with the bicarbonate solution and were ready for use as target cells in the haemolytic plaque assay of Jerne performed as before⁸. The indirect plaque forming cells were revealed by use of a rabbit anti-mouse IgG serum shown to react with IgG1, IgG2a, IgG2b, and IgG3 on immunodiffusion. The serum was used at a dilution of 1/200. IgG (7S) PFC were obtained by subtracting the direct PFC from the total number of PFC. Statistical analysis with Student's *t* test.

PFC on day 7 (Fig. 1). The spleens of non-immunised mice did not contain PFC to AGCT-SRBC spontaneously, and mice immunised with AGCT-KLH did not have a significant increase in the number of PFC to unsubstituted sheep red blood cells (SRBC).

To determine whether a nucleoside-IgG2a conjugate would suppress the appearance of anti-nucleoside antibody forming cells, mice were treated with 0.2 mg of tolerogen (AGCT-IgG2a) immediately before immunisation. They developed virtually no direct or indirect PFC (Fig. 2). Similar results were obtained when the tolerogen was given intravenously (i.v.) 10 d before immunisation (Table 1).

We then determined whether one can detect direct PFC to individual nucleosides in mice immunised with all four nucleosides, to allow a study of the nucleoside specificity of the tolerance. Seven BALB/c mice were injected with 0.2 mg of G-IgG2a. Ten days later, together with untreated controls, they were immunised intraperitoneally (i.p.) with 0.2 mg of AGCT-KLH in complete Freund's adjuvant, and the direct haemolytic plaque assay for all four nucleosides together (AGCT-SRBC), as well as for individual nucleoside SRBC targets, was performed 6 d later. Mice immunised with AGCT-KLH developed PFC to each of the four nucleosides (Table 2). The number of PFC was greatest for G and was much smaller for A than for any of the other nucleosides. Mice made tolerant by G-IgG2a had a specific suppression of antibody forming cells to this nucleoside only.

Several points are worth emphasis. First, when tolerance was induced in BALB/c mice by injection of nucleoside-IgG2a conjugates, the mechanism involved a reduction in the number of antibody forming cells and not simply the removal of preformed circulating antibody, suggesting that a similar mechanism may have occurred in (NZB/NZW)F1 mice made tolerant by nucleoside-IgG conjugates⁷. Second, when mice were given the G-IgG2a tolerogen and immunised with AGCT-KLH, they developed PFC to any nucleoside not present on the tolerance inducing carrier, demonstrating the exquisite specificity of tolerance at the cellular level. Third, tolerance was induced by nucleoside-IgG in terms of both direct and indirect PFC. It was also notable that while antibody forming cells to individual nucleosides could be detected readily in control mice

Fig. 2 Suppression of anti-nucleoside PFC formation by nucleoside-IgG conjugate. Each bar represents the geometric mean ($\pm$ s.e.) PFC per spleen of a group of five BALB/c mice either immunised i.p. with 0.2 mg of AGCT-KLH in complete Freund's adjuvant without pretreatment, or treated with 0.2 mg of AGCT-IgG2a immediately before the immunisation. Both AGCT-SRBC, prepared as described in the legend to Fig. 1, and unsubstituted SRBC were used as target cells in the haemolytic plaque assay done 6 d after immunisation. *a*, Direct PFC on day 6; *b*, indirect PFC on day 7.

Table 1 Effect of nucleoside-IgG2a conjugate on appearance of anti-nucleoside antibody forming cells

Treatment 10 d before immunisation	Direct (AGCT) PFC per spleen on day 7	<i>P</i>	Indirect (AGCT) PFC per spleen on day 7	<i>P</i>
None	10,173 ± 1,867		1,862 ± 594	
AGCT-IgG2a	1,888 ± 480	<0.001	498 ± 202	<0.01

Seven BALB/c mice were treated with 0.2 mg of AGCT-IgG2a, given i.v. and, together with seven untreated mice, were immunised i.p. with 0.2 mg of AGCT-KLH in complete Freund's adjuvant 10 d later. Direct and indirect PFC were measured on day 7, as described in the legend to Fig. 1. Values are means ± s.e.

Table 2 Nucleoside specificity of tolerance

Treatment 10 d before immunisation	AGCT-SRBC	<i>P</i>	Direct PFC per spleen on day 6	<i>P</i>	C-SRBC	T-SRBC
			A-SRBC			
None	19,970 (7,283)		1,055 ± 922		6,706 ± 3,730	7,943 ± 4,546
G-IgG2a	12,751 (7,283)	>0.4	1,535 ± 689	<0.01	5,824 ± 4,791	6,067 ± 2,066

Seven BALB/c mice were treated with 0.2 mg of G-IgG2a and, together with seven untreated mice, were immunised i.p. with 0.2 mg of AGCT-KLH in complete Freund's adjuvant 10 d later. Individual nucleoside-SRBC target cells were prepared as in the legend to Fig. 1, but in each case 10 mg of nucleoside were oxidised in 1.0 ml of 0.1M sodium periodate. Direct PFC were measured 6 d after immunisation. Values are means ± s.e.

immunised with all four nucleosides on the immunogenic carrier, there was some variation in the number of PFC specific for each nucleoside. This reflected at the cellular level of the immunodominance of guanosine and the low immunogenicity of adenosine that we have noted previously for serum antibody responses⁴. Finally, from a technical point of view, the modifications of the technique of Erlanger and Beiser⁵ to link nucleosides to sheep cells should be noted. The ionic strength had to be maintained to prevent lysis. The use of 0.15 M bicarbonate did this and provided a suitable pH for the Schiff base formation. The use of *t*-butylamine borane complex in place of sodium borohydride was important in preventing damage to the erythrocytes during reduction of the Schiff base, and the reduction time was brief.

The immune response to nucleic acid antigens is important from at least two points of view. First, since anti-nucleic acid antibodies are involved in autoimmune disease⁶, the suppression of this response can be of therapeutic importance; and second, strain differences in the ability of mice to respond to nucleic acid antigens have been observed⁹ and might offer the opportunity to study the genetic basis of both immunity and tolerance to defined determinants of naturally occurring antigens. The development of an assay that permits the detection of antibody forming cells to either all four nucleosides simultaneously or to individual nucleosides is useful for the study of these phenomena.

This work was supported by the US NSF, NIH and the Massachusetts Lupus foundation. We thank Ms L. Kilham for technical assistance.

T-cell cytotoxicity in the absence of viral protein synthesis in target cells

CYTOTOXIC T cells lyse only those virus infected target cells *in vitro* which express, in addition to the viral antigen(s), those *K* or *D* region products of the major histocompatibility complex (MHC) which were present during anti-viral sensitisation *in vivo*. This 'associative recogniton' by cytotoxic T cells could reflect the interaction of two T-cell receptors with specificity for target *K* or *D* gene products and independently for the viral antigen, or one receptor

Fig. 1 Separation of Sendai virus envelope protein on SDS-polyacrylamide gels. Sendai virus (8 mg ml^{-1}) in phosphate-buffered saline without Mg or Ca (PBS-A), 1.5×10^6 haemagglutinating units (HAU) per ml were treated with 0.25% NP 40 for 15 min at 20°C (ref. 6). The suspension was centrifuged at $120,000g$ for 1 h at 4°C to remove partially disrupted virions and nucleocapsids. The supernatant was dialysed for 4 d at 4°C against twice daily changes of PBS-A using spectrophor 2 tubing (Raven Scientific). The reassembled membrane particles were concentrated by centrifugation at $120,000g$ for 1 h at 4°C and the pellet was resuspended in PBS-A. Envelopes were active in assays for haemagglutination⁷, neuraminidase⁸ and haemolytic activities⁹. Envelopes were analysed by SDS-polyacrylamide electrophoresis by the method of Laemmli¹⁰ using 10% gels. P, polymerase; HN, haemagglutinin; NA, Neuraminidase; Fi, fusion factor; M, M-protein.

with specificity for virally altered *K* or *D* region products (see ref. 1 and refs therein). There are various ways that the MHC antigens could be altered, including 'modification from within', where the virus modifies host protein synthesis by interfering with transcription², translation or post-translational glycosylation; or 'modification from without' where enzymic or chemical alteration of cell membrane proteins are induced by virus activity at the cell surface. In this report we show that inactivated Sendai virus or isolated Sendai virus envelopes can serve to modify a cell and make it a specific target for Sendai-immune T-cell killing, thus excluding the possibility of 'modification from within' in this system.

Sendai virus-primed BALB/c spleen cells, boosted *in vitro* with syngeneic infected blast cells, specifically killed Sendai virus-infected syngeneic target cells; primed spleen cells boosted with syngeneic non-infected cells did not (Table 1). Killer cells after secondary stimulation were T cells as shown by treatment with anti-Ly-sera (U. K. and P. Beverley, unpublished). Three approaches were used to show that synthesis of viral protein is not required in the target cell in order for it to be killed by virally sensitised T cells. First, cells incubated with ultraviolet-irradiated Sendai virus were lysed by sensitised T cells (data not shown). Second, cells exposed to purified Sendai virus, inactivated with β -propiolactone—which abolishes induction of protein synthesis by inactivated particles³—also proved to be effective target cells (Table 1). Treatment with β -propiolactone reduced the number of plaque forming units by 10^8 . Since the ratio of particles to plaque forming units would be expected to be no better than 10:1 (J. Skehel, personal communication) and target-to-particle ratio was 1:10⁶, it follows that, at most, one in a thousand cells were infected with a live virus. Sendai virus specific killer cells generated by secondary stimulation *in vitro* lyse only *H*-2-compatible infected target cells (U. K., unpublished) and the same restriction is seen using target cells incubated with inactivated Sendai virus (Table 2). Third, cells exposed to isolated envelopes from Sendai virus, which contained mainly the two surface glycoproteins with a very small amount of nucleocapsid and almost no detectable M-protein (Fig. 1), were susceptible to T cell-mediated lysis. To exclude nonspecific effects of the Sendai envelopes on target cells, influenza virus-specific cytotoxic T cells were tested on these target cells, and found to be ineffective (Table 3).

In several virus infections, target cell formation requires translation of early viral proteins¹¹⁻¹³, glycosylation¹⁴, and

Fig. 2 T cell-mediated lysis of P-815 target cells exposed to dilutions of purified Sendai virus inactivated with β -propiolactone (B-PL). Sendai virus was grown in the allantoic cavity of 10-d-old embryonated fowl eggs and purified by centrifugation through a sucrose gradient (20–55% in PBS-A). The virus-containing band was collected and concentrated by centrifugation at 120,000g for 1 h. Inactivation was achieved by incubating the purified virus (2 mg per ml, 4×10^4 HAU per ml, $1 \mu\text{g} \approx 10^{11}$ virus particles) for 18 h at 4 °C with β -propiolactone (Sigma) at a concentration of 0.025%. β -propiolactone was inactivated by incubation for 30 min at 37 °C. Inactivation was tested by egg infectivity titration¹⁵. ○—○, Lysis of P-815 cells exposed 2 h before test with dilutions of B-PL-Sendai virus (100 μg virus per 10^6 cells, about 10^6 particles per cell). □, P-815 targets infected overnight with 20 PFU per cell (1 PFU ≤ 10 particles). ▽, Non-infected P-815 control cells. Assay conditions identical to Table 1, incubation time 3 h, ratio of killer-target cells, 5:1.

expression of viral proteins on the cell surface. The ability of Sendai virus to by-pass these processes may be due to its unique capacity to mediate cell-cell fusion, which could allow the insertion of large amounts of virus glycoprotein into the target cell membrane. From the dose-response curve (Fig. 2) of target cell formation with dilutions of β -propiolactone inactivated Sendai virus, it can be seen that about 10^6 particles per target cell were required to induce

BALB/c mice were immunised to Sendai virus by i.p. injection of 0.2 ml allantoic fluid containing 10^7 plaque forming units (PFU) of virus³. Six weeks later spleens were collected and incubated in RPMI medium containing 10% foetal calf serum, glutamine and 5×10^{-6} M 2-mercaptoethanol in 2 ml well linbro plates in presence of stimulated cells. Stimulator cells were prepared by incubation of spleen cells in culture medium containing $2.5 \mu\text{g ml}^{-1}$ concanavalin A (con A) for 48 h followed by overnight infection with 20 PFU per cell Sendai virus and 2,000 rad irradiation. 5×10^6 responder cells were incubated with 5×10^5 stimulator cells. Cytotoxic T cells were collected from cultures 4–7 d later⁴ and a ^{51}Cr release assay was performed with 5×10^3 syngeneic tumour target cells per well⁵. Target cells were a, ^{51}Cr labelled non-infected P-815 cells; b, P-815 cells infected overnight with 20 PFU per cell Sendai virus; c, P-815 cells pre-incubated for 2 h with β -propiolactone (B-PL) inactivated (see legend Fig. 2), purified Sendai virus in a protein concentration of $50 \mu\text{g}$ per 10^6 target cells; d, P-815 cells pre-incubated for 2 h with Sendai envelope (env.) proteins (see legend to Fig. 1) in a protein concentration of $50 \mu\text{g}$ per 10^6 target cells. Results are from triplicate assays; S.E.M. were always less than 3. Spontaneous lysis, which did not exceed 15–20%, is subtracted.

Table 2 Lysis of target cells treated with β -propiolactone inactivated Sendai virus is *H*-2 restricted

Responder cells	Stimulator cells	P-815 S-B-PL (<i>H</i> -2 ^{dd})	L-929 S-B-PL (<i>H</i> -2 ^{kk})	EL-4 S-B-PL (<i>H</i> -2 ^{bb})
BALB/c normal (<i>H</i> -2 ^{dd})	BALB/c con A treated blast, Sendai infected	3.1	1.4	2.5
BALB/c immune (<i>H</i> -2 ^{dd})	BALB/c con A treated blasts, Sendai infected	46.1	1.5	11.9
CBA immune (<i>H</i> -2 ^{kk})	CBA con A treated blasts, Sendai infected	2.4	30.6	3.0
C57BL6 immune (<i>H</i> -2 ^{bb})	C57 BL6 con A treated blast, Sendai infected	—	3.8	32.5

Conditions of immunisation and *in vitro* restimulation were as for Table 1. Cells were collected and tested on culture day 6. Target cells were incubated with B-PL-virus, in a protein concentration of 50 μ g per 10⁶ target cells. Results are from triplicate assays, ratio of killer-target cells is 20:1, incubation time 4 h.

a comparable degree of killing as seen with infected target cells. Since the percentage of particles which actually fuse with the target cells is unknown, the number of fused particles per cell necessary for target cell formation cannot be estimated. Failure to use sufficiently high concentrations of virus during target cell incubation may explain previous negative findings (ref. 12, and U.K., unpublished).

β -propiolactone-Sendai virus-treated target cells were lysed to a similar extent as target cells incubated with live virus, but target cells which were produced with Sendai virus envelope vesicles were consistently lysed at a lower plateau level. Two explanations are possible. There could be two populations of Sendai virus specific cytotoxic T cells

within'. If there are alterations of *H*-2 gene products these must occur from without, at the cell surface. Envelopes contain neuraminidase activity, but cleavage of neuraminic acid seems not to change the *H*-2 surface antigen specificity^{16,17}. We do not know if there are other residual enzyme activities such as proteases or glycosidases remaining in the envelopes. It is also possible that cross-linking of sialic acids by the viral haemagglutinin might change the surface distribution of *H*-2, and sometimes create effective target antigens.

Which then are the viral antigens on cell surfaces recognised by the T cells? Recent studies on influenza virus-specific CTL have suggested that the M-protein which is

Table 3 Virus-specific lysis of target cells incubated with inactivated Sendai virus or Sendai virus envelopes

Responder cells (BALB/c, (C3H $\times$ DBA/2) F₁) were collected from mice injected i.p. 6 weeks previously with 10⁷ PFU Sendai virus or influenza virus. The influenza strain A/Jap/Bel/305/57 (H₂N₂) a recombinant of A/Jap/305/57 (H₂N₂) and A/Bel/42 (H₀N₁) (kindly supplied by Dr J. Skehel) was used. Conditions of *in vivo* sensitisation and *in vitro* boosting of cells were similar to those used for secondary cytotoxic T-cell generation against Sendai virus. Stimulator cells were BALB/c lymphocyte blasts after 48 h incubation in 50 μ g ml⁻¹ lipopolysaccharide containing medium or P-815 tumour cells. Stimulator cells were infected overnight with 20 PFU per cell and irradiated with 2,000 rad (blasts) or 8,000 rad (P-815). Ratio of stimulator to responder cells and ⁵¹Cr release assay conditions were identical to those described in the legend to Table 1.

with receptors for different viral antigens; however, antigens on envelope-treated target cells are at least partially shared with those of infected target cells since the latter compete in cold cell inhibition tests with the lysis of target cells exposed to Sendai virus envelopes (data not shown). The second possibility is that the envelope vesicles are less active in fusing with the target cell membrane; this is the more likely explanation since the β -propiolactone inactivated virus was active in cell-cell fusion, while the envelopes were not.

These results rule out, at least for Sendai virus infection, formation of an 'altered self' by a 'modification from

not glycosylated and not expressed on cell membranes may contribute to target specificity¹⁸. This is very unlikely for Sendai virus since the envelope preparations contain only two glycoproteins, one with neuraminidase and haemagglutinin activity and the other with fusion activity.

These results show for the first time that target cells for virus-specific T-cell lysis can be prepared with vesicles containing essentially only viral surface glycoproteins and that viral protein synthesis is not required for target cell formation.

We thank Drs Martin Raff and Peter Beverley for helpful discussion and Rowan Coyle and John Sever for technical

assistance. U.K. was supported by Deutsche Forschungsgemeinschaft and M.W. by the American Heart Association.

Cellular inactivation by ultrasound

THE lethal effect of ultrasound (US) on mammalian cells has received relatively little attention. Understandably, potential genetic aspects of US have been of prime concern to physicians who use US as a diagnostic tool; at the average power densities involved ($\ll 1 \text{ W cm}^{-2}$) little, if any cell killing is to be expected. There have been sporadic attempts to use higher intensities ($\sim 1 \text{ W cm}^{-2}$) as a treatment modality in cancer therapy^{1,2}, but those experiments seem to have been based on inadequate cellular studies. The effects of US usually were evaluated in terms of morphological criteria rather than on quantitative determination of the loss of viability as measured by colony formation. There are few reports of the effects of US on survival of mammalian cells^{3,4}, and none specifically examine hyperthermic interaction. With the increased interest in hyperthermia for tumour therapy, attention has been directed towards the use of ultrasound to achieve tumour heating. In preliminary experiments in which US was used to heat the EMT6 sarcoma and KHJ carcinoma in mice, we found a high percentage of tumour cures with short (~ 30 min) treatments at temperatures ($43-44^\circ\text{C}$) where *in vitro* results of hyperthermia-induced cell killing⁵⁻⁷ would not have led to a prediction of any cures. We therefore initiated an investigation of the effects of US on survival of Chinese hamster cells to see if direct cell killing by US could explain our *in vivo* results, or, as in the case of radiofrequency (RF) electromagnetic heating, we would be forced to invoke host response⁸. In particular, we examined the thermal and non-thermal components of cellular inactivation by US. We report here that there is a definite non-thermal cytotoxic effect of US. Its relative contribution to cell killing is a highly nonlinear function of the temperature of the cellular milieu. The survival curves show clearly that, beyond an initial threshold, small changes in temperature and/or US intensity can give rise to impressive changes in survival values. The threshold nature of the data strongly suggests that by means of overlapping beams, ultrasound energy could be delivered to tumour tissue to achieve massive cell killings while

sparing normal tissue outside the tumour volume to a degree far exceeding that of conventional techniques.

Chinese hamster cells (HA-1) of ovarian origin were maintained in Eagle's MEM supplemented with 15% foetal calf serum, penicillin, and streptomycin. The cultures were kept in a humidified incubator with a mixture of 95% air and 5% CO_2 , and were routinely checked for mycoplasma. To maximise the transmission of the acoustic energy and hence minimise heat induced by absorption of US, cells were grown as monolayers in specially designed stainless steel dishes with Mylar bottoms ($130 \mu\text{m}$ thick). Approximately 8×10^4 cells were seeded within a confined area (1.6 cm in diameter) on the thin Mylar film; experiments were always performed on the third day after plating when the cell density reached approximately $5 \times 10^5 \text{ cells cm}^{-2}$ and the cells were still in exponential growth. Plating efficiencies of cells trypsinised from the Mylar film were 70-90%. Some experiments were performed with cells in suspension; as far as possible, the geometry was identical to that used for attached cells. The cloning technique of Puck and Marcus was used to determine the fraction of viable cells. The US irradiating system consisted of a laboratory-developed signal generator and power amplifier driving a piezo-electric transducer (Mettler Electronics). The transducer was mounted on the frame

Fig. 1 Plating efficiencies (normalised to untreated controls) against US intensity. Cells were irradiated for 30 min at a, 37°C ; b, 43°C . Error bars in this and the succeeding figures show s.e.m. Plating efficiency is defined as (no. colonies per dish/no. cells plated per dish) $\times 100$. Cells plated per dish represents countable cells obtained by enzymic removal from Mylar after treatment.

of a specially designed dish holder, in a circulating hot water bath (Forma-Temp. Jr), so that alignment between cells and the transducer was accurately reproducible. The Mylar bottom of the dish was always in direct contact with circulating water of the desired temperature. The cells were irradiated at a distance of 13 cm from the transducer (3.5 cm diameter). The operating frequency was 1 MHz and the signal was pulse-modulated at about 1,000 cycles s^{-1} (duty cycle 60%). The irradiation field was 1.6 cm in diameter at this source-target distance; the spatial uniformity of the field intensity was within $\pm 20\%$ as measured by an absorbing probe. This probe consisted of a 22 gauge needle with a thermistor mounted inside the top; the tip was surrounded by a cylinder of silicon rubber (3 mm in diameter and 5 mm in length). The probe was calibrated by RCA laboratories, Princeton, New Jersey; the intensity measured included any reflected contribution. Agitation minimised any standing wave formation, however. The temperature of the water bath was maintained to $\pm 0.1^\circ C$; the temperature difference between the circulating water and the medium inside the dish was less than $0.1^\circ C$ even at US intensities of $2 W cm^{-2}$. The time required to reach thermal equilibrium was about 2–3 min; this is included in the quoted times of heating and/or US irradiation. Temperature measurements in the presence of US fields were obtained using thermocouples encased in 28 gauge needles. At intensities of approximately $0.7 W cm^{-2}$ at the measuring instrument, we saw no interaction of US and the sensor. When higher intensities were used, such interaction was observed and had to be taken into account; an infrared pyrometer was then used to measure the temperature of the medium inside the dish.

Fig. 2 Plating efficiencies (normalised to untreated controls) against temperature. *a*, Cells exposed for 30 min to heat alone; *b*, cells irradiated for 30 min with US ($2 W cm^{-2}$) at the indicated temperatures.

For each experiment, survival values of cells exposed to heat treatment in the absence of US irradiation were measured; the results were all in good agreement with previously published data⁶ and were used as thermal controls. Any cytotoxicity above these control values is attributed to non-thermal mechanisms.

Monolayers of cells were exposed to pulsed US radiation for 30 min at various average intensities and at water bath temperatures ranging from 37 to 45 °C. Plating efficiencies (all normalised to those of untreated controls) of cells irradiated at 37 °C and 43 °C are shown in Fig. 1. The cytotoxicity of US irradiation had a threshold when plotted against average acoustic intensity. This threshold intensity was temperature dependent: at 43 °C it was lower than

Table 1 Effect of ultrasound radiation on cell number

Average intensity ($W cm^{-2}$)	Countable cells on Mylar after 30 min US irradiation (% of unirradiated controls)	
	37 °C	43 °C
0.75	100	100
1.5	18	20
2.0	5	5

37 °C. Cells were then exposed at various temperatures either with or without pulsed ultrasound at an average intensity of $2 W cm^{-2}$. Figure 2 shows the plating efficiencies as a function of water bath temperature. Survival of cells exposed simultaneously to heat and ultrasound was lower than that of cells exposed to heat alone. Plotted against temperature, the cytotoxicity of US irradiation at a constant average intensity again showed a threshold.

In addition to changes in plating efficiency, there was also a reduction in cell number, showing the occurrence of immediate cell lysis. Table 1 indicates the percentage of cells which were attached to the Mylar after 30 min exposure to US, with respect to the untreated control. The cell number includes both viable and non-viable cells. In contrast to plating efficiency, the fraction of cells lysed showed no significant temperature dependence between 37 and 43 °C. Survival values, after correction for cell lysis, are shown in Fig. 3 for one set of experiments. The number of cells recovered from the supernatant was negligible.

The possibility that these results were artefact of the attachment of cells to the Mylar was ruled out by the finding that cells in suspension responded similarly to US irradiation (data not shown). The nature of US-induced cell damage is not clearly understood. In general, US effects are classified under thermal, cavitation or 'other'⁹⁻¹¹. In the experiments described above, the magnitude of thermal effects has been evaluated independently, since the macroscopic temperature in each case was established by the hot water bath and not by the US intensity. The cell killing over and above that caused by this temperature is clearly due to non-thermal effects. These non-thermal effects may be divided into temperature-dependent and temperature-independent components. Cell lysis is largely temperature-independent, while cell inactivation, as measured by the reduction in plating efficiency, results at least in part from temperature-dependent effects. Cavitation played an important part; this was shown in experiments in which the average US energy was kept constant, but pulse duration and repetition frequency were varied. With pulses of less than 1 ms, much less cell lysis and cell death were seen; 1 ms is about the minimum time required for the onset of cavitation¹². Even much shorter pulses induced considerable lysis and cell death, however; hence other phenomena such as, for example, acoustic streaming were involved.

Fig. 3 Surviving fractions of cells exposed to US for 30 min at various temperatures and intensities. *a*, Heat alone; *b*, 1 W cm⁻²; *c*, 2 W cm⁻²; *d*, 2.2 W cm⁻². Surviving fraction (SF) is defined as (cell no. after treatment/cell no. before treatment) × (plating efficiency).

The dramatic temperature-dependent changes in plating efficiencies observed (Figs 1 and 2) are unlikely to be related to changes in the physical action of ultrasound, but rather to intracellular changes. Experiments in ours and other laboratories have demonstrated a variety of temperature-related changes in the response of cells to cytotoxic agents¹³, to hypo- or hypertonic environments¹⁴, and to membrane-specific antibiotic amphotericin B (ref. 14). These changes, which probably involve modification of cellular membranes, occur in the range of 41–43 °C, and all are in the direction of appreciably and sometimes dramatically greater sensitivity to the external challenge. Thus, it is not unreasonable to find that the cells' response to US also changes drastically with temperature. It must be kept in mind, however, that the observations of thermal interactions depend critically on the particular parameters of US irradiation. Intensity variations, frequency variations (or modulation) and changes in pulse width can shift the thresholds appreciably. This makes it imperative that, for comparison of results, conditions be standardised, and that the details of US irradiations be reported carefully.

The shapes of the survival curves (Figs 1–3) suggest that US may be a very useful tool in the eradication of localised tumours. Since US can readily be focused, it should not be difficult to obtain 'dose distribution' such that temperature and intensity thresholds are exceeded only within a hypothetical volume. Within that volume, extensive cell killing would then be effected, while in the surrounding normal tissue very little cytotoxicity would be expected. In that sense, then, US would differ greatly from X-ray (or even high LET particle) therapy, as well as from focal ultrasound ablation¹⁵, where normal tissue toxicity outside the tumour volume is frequently the treatment-limiting consideration. It would also differ from RF-induced current

heating, where cell inactivation seems to be largely (or exclusively) through thermal mechanisms⁸. The tumour experiments referred to earlier are consistent with this expectation: in mice which had been cured of their tumours by US and which were sacrificed as late as 180 d after treatment, little or no evidence of normal tissue damage was seen (Fajardo, Marmor and Hahn, unpublished). We are not sure, however, that the tumour cures can be explained entirely on the basis of this direct US-related cell killing: at the intensity levels of the tumour irradiations, at least the peripheries of the tumours should have been below the cytotoxic threshold levels found *in vitro*.

We thank Drs R. S. Mezrick and D. H. R. Vilkomerson for calibrating our probes, and Mr D. Pounds and Ms E. Shiu for technical assistance. This work was supported by US Public Health Service grants.

Effect of human interferon preparations on lymphoblastogenesis in Down's syndrome

THE best characterised properties of human interferon, its antiviral (AV) and cell multiplication inhibitory (CMI) activities, are controlled, in an unexplained manner, by genes on chromosomes 21 (refs 1–4; 14–16). Human and animal interferons have various immunosuppressive effects^{3–10}, among them the inhibition *in vitro* of DNA synthesis in activated lymphocytes¹¹. Using mitogen- and antigen-stimulated lymphocytes from normal subjects (disomic 21) and others with Down's syndrome (trisomic 21), we have found that DNA synthesis is inhibited to a greater degree in the latter by both fibroblastoid and leukocyte interferons. We suggest that this property is also regulated by genes on chromosome 21.

Blood samples were obtained from ten subjects previously diagnosed with Down's syndrome, and from seven normal volunteers. The former were karyotyped, using quinacrine staining, to verify trisomy of chromosome 21. Lymphocytes were separated on a Ficoll-Hypaque gradient. Blast formation was stimulated either with phytohaemagglutinin (PHA) or in a one-way mixed lymphocyte reaction (MLR). Serial dilutions of two different interferon preparations, one from a poly(I)-poly(C)-induced fibroblastoid cell line maintained in our laboratory³ and one from virus-induced leukocytes, were added at the beginning of culture. Serially diluted

dilution of interferon preparation that produces 50% inhibition of DNA synthesis in trisomic 21 lymphocytes

Sensitivity = $\frac{\text{dilution of interferon preparation that produces 50\% inhibition of DNA synthesis in trisomic 21 lymphocytes}}{\text{dilution of interferon preparation that produces 50\% inhibition of DNA synthesis in disomic 21 lymphocytes}}$

Two trisomic 21 and one disomic 21 samples were tested on each occasion. Human fibroblast interferon was prepared by inducing human fibroblastoid cultures with poly (I)·poly (C). This interferon preparation was centrifuged at 100,000g for 1 h to remove any SV40 virus particles. Purified human leukocyte interferon¹³, prepared by Dr K. Cantell, was supplied by Dr M. Krim. Both interferon preparations were verified by Dr E. Havell as fibroblast and leukocyte interferon, respectively, by antibody neutralisation tests¹². Lymphocytes were cultured and stimulated with PHA or by allogeneic cells as described in Tables 2 and 3, and were treated with serially diluted interferon preparations for the duration of the experiments. Mock interferon preparations of the appropriate dilution were included with the experiments.

mock interferon, prepared in the same way as fibroblastoid interferon, but without inducer, was added to control cultures. DNA synthesis, an indicator of lymphoblastogenesis, was determined by measuring the incorporation of tritiated thymidine into the trichloroacetic acid (TCA)-precipitable cell fraction. To ensure that the interferon preparations did not alter the uptake of thymidine into the

Figures are average c.p.m. from duplicate cultures.

Lymphocytes were separated from heparinised blood on a Ficoll-Hypaque gradient (Pharmacia) and washed three times in Ca^{2+} and Mg^{2+} free Hanks basic salt solution (Gibco). Duplicate sets of cultures were grown in round bottomed Microtest plates (Falcon) using RPMI 1640 medium (Gibco) containing 10% foetal calf serum (Flow), 1% chlortetracycline and 0.1% PHA-P (Difco). Each well contained 5×10^4 cells in 0.2 ml. After 72 h, 0.01 ml of ^3H -thymidine (Schwartz-Mann, specific activity 1.9 Ci mmol⁻¹, 0.1 mCi ml⁻¹) was added. Four hours later, 20 μl of 20% sodium dodecyl sulphate was added to lyse the cells. The contents of each well were placed on glass fibre filter papers, washed three times in 5% TCA to precipitate the DNA and rinsed three times with 95% ethanol. After drying, the papers were placed in liquid scintillation vials with Spectrafluor (6 g PPO and 75 mg POPPOP per l toluene, Amersham/Searle) and counted for 10 min, or to 1% error.

cell, the amount of radioactivity in the soluble fractions was also measured; no difference was found between the interferon-treated and untreated cultures.

In similar experiments, human interferon preparations were applied to PHA-stimulated murine spleen cells, while mouse interferon was added to human lymphocyte cultures. No species cross-reactivity was observed.

Trisomic 21 lymphocytes, whether stimulated by PHA or by allogeneic cells, were more sensitive than disomic 21 lymphocytes to the suppression of DNA synthesis by both interferon preparations (Table 1). The number of copies of chromosome 21 had no effect on the maximum levels of DNA synthesis obtained in the mock interferon-treated controls (Table 2). There was also no significant difference ($P > 0.5$) in maximum levels of DNA synthesis between the various donor combinations in the MLR, that is, it made no difference which genotype, trisomic 21 or disomic 21, was the stimulator or responder (Table 3). These results

Table 3 DNA synthesis in one-way mixed lymphocyte reactions

Figures are average c.p.m. from duplicate cultures. T21, trisomic 21; D21, disomic 21.

After separation, lymphocytes to be used as stimulator cells were treated for 30 min with mitomycin C ($25 \mu\text{g ml}^{-1}$), and washed twice in RPMI 1640 medium. Duplicate sets of cultures consisted of 5×10^4 stimulator and 5×10^4 responder cells in each well with 0.2 ml of complete medium. ^3H -thymidine (0.01 ml) was added after 96 h and cultures were terminated at 120 h.

indicate that the higher sensitivity of trisomic 21 lymphocytes to human interferon preparations is due to the presence of an extra copy of chromosome 21, and not to a changed sensitivity to antigenic or mitogenic stimuli.

The lymphocytes of one individual, J.S., who had been suspected to have Down's syndrome, showed a response to interferon similar to those of disomic 21 controls (Table 1); karyotyping revealed that J.S. had only two copies of chromosome 21. All trisomic 21 lymphocytes were more sensitive to the inhibitory effects of the human interferon preparations. This suggests that suppression of *in vitro* lymphoblastogenesis by human interferon, like its AV and CMI activities, acts through genes on chromosome 21. This implies that the various actions of human interferon applied to human cells are mediated through a common cellular pathway, the exact nature of which will probably not be known until the specific gene product(s) of chromosome 21 has been identified. Because interferons have not been purified and isolated conclusively, it remains to be seen whether the different effects of interferon preparations are due to one or more molecules. Until purification is achieved, and the respective antibodies prepared, it should be possible to assay human interferon preparations on the basis of their action through chromosome 21, in order to distinguish them from other macromolecules with similar actions, such as other lymphokines.

The developmental and metabolic abnormalities associated with Down's syndrome are probably due to the

presence of an extra chromosome and the resulting imbalance of gene products. Since trisomic 21 cells are hypersensitive to the CMI activities of human interferons, including the inhibition of lymphoblastogenesis, it is possible that some of the developmental and immunological defects associated with Down's syndrome are due to an abnormal interferon response.

We thank Dr C. Tan for karyotyping the Down's syndrome subjects, Dr E. A. Havell for characterising the interferon preparations immunologically and the MRC of Canada and IROI CA19721-01 for support. Y.H.T. is an NCI Scholar of Canada.

Dystrophic mice show age related muscle fibre and myelinated axon losses

ALTHOUGH many differences between age matched normal and dystrophic animals have been found, there have been few demonstrations of a time related quantitative change from normal to a characteristically dystrophic situation within the dystrophic strain itself. Here we report such a change—normal numbers of muscle fibres present in young dystrophic mice were rapidly lost, such that older animals showed the reduced number of muscle fibres characteristic of murine dystrophy. Although these losses began after a demonstrable loss of myelinated axons had occurred, it is not possible to say if the loss of muscle fibres was a result of the loss of nerve fibres.

The major practical problem in this study was that of obtaining animals of known dystrophic genotype of less than 3-4 weeks of age. The use of the C57BL/6J dy^{2J}/dy^{2J} strain of dystrophic¹ mice overcame this problem; affected animals occasionally breed and produce one or two litters. Thus, with animals of known dystrophic genotype, early developmental observations can be carried out.

A detailed investigation of the growth and development of normal 129ReJ $+/+$ and dystrophic 129ReJ dy/dy mouse muscles^{2,3} revealed a progressive loss of muscle fibres from the earliest age point at about 3 weeks. By about 6 weeks 40-50% of the muscle fibres, when compared with normal, had been lost from the respectively fast⁴ and slow-twitch⁴ extensor digitorum longus (EDL) and soleus muscles. Harris *et al.*⁵ and Bradley and Jenkinson⁶ have published conflicting reports on the number of myelinated axons in the nerves of 129ReJ dy/dy dystrophic mice. A 20% reduction of myelinated axons was reported by Law and Atwood⁷ in 129ReJ dy/dy dystrophic mouse soleus nerves. Bray and Aguayo⁸ observed a slight but probably not statistically significant reduction in the number of

myelinated axons in the nerve to the medial gastrocnemius muscle of 129B6F₁ dy/dy dystrophic mice.

Each of the studies mentioned above used a light microscope counting technique for axon numbers. We have found that these techniques often lead to an underestimation by 10-20% of the number of myelinated axons present when compared with counts obtained from low-power electron micrographs of the same nerve. We therefore used low-power electron micrographs of the nerves of male and female C57BL/6J $+/+$ normal and C57BL/6J dy^{2J}/dy^{2J}

Fig. 1 *a* Muscle fibre counts from normal (+) and dystrophic (●) soleus muscles as a function of age. Each point represents the mean $\pm$ s.e. of at least 6 observations. The 1 week normal and dystrophic values were not statistically significantly different (Student's *t* test $P=0.05$ was used for all significance tests). At 15 and 72 weeks the percentage reductions in dystrophic fibre numbers were 37.4% and 33.8% respectively and the differences between the dystrophic and normal mean values at these age points were significantly different. *b*, Muscle fibre counts from normal (+) and dystrophic (●) extensor digitorum longus muscles. Each point represents the mean $\pm$ s.e. of at least 6 observations. The differences between the 1, 2 and 4 week normal and dystrophic values were not statistically significant. At 15 and 72 weeks the percentage reductions in dystrophic fibre numbers were 45.9% and 44.6% and the differences between the dystrophic and normal mean values at these age points were significantly different.

dystrophic animals aged 1–72 weeks. The nerves used in this study were those innervating the fast-twitch plantaris⁹ and slow-twitch⁴ soleus muscles. They both presented easily accessible, anatomically distinct, unifascicular portions,

Fig. 2 *a* Myelinated axon counts from normal (+) and dystrophic (●) soleus nerves as a function of age. Each point represents the mean $\pm$ s.e. of at least 6 observations. The regression line for normal nerves was $y = -0.035x + 77.7$ and for dystrophic $y = -0.152x + 61.9$. The regression coefficient for normal nerves was not significantly different from zero whereas that for dystrophic nerves was. At 1 week the percentage reduction of dystrophic myelinated axons was 18.0% and at 72 weeks 30.8% and the difference between the normal and dystrophic mean values was statistically significant at every age point. The difference between the 1- and 72-week dystrophic values was significant and the percentage reduction in this case was 16.3%. *b*, Myelinated axon counts from normal (+) and dystrophic (●) plantaris nerves. Each point represents the mean $\pm$ s.e. of at least 6 observations. The regression line for normal values was $y = 0.074x + 69.2$ and for dystrophic values $y = 0.189x + 61.0$. The regression coefficient for normal nerves was not significantly different from zero whereas that for dystrophic nerves was. At 1 week the percentage reduction of dystrophic myelinated axons was 7.6% and at 72 weeks 24.3%. The differences between normal and dystrophic 1- and 2-week mean values were not statistically significant, at every other age point the differences were significant. The difference between the 1-week and 72-week dystrophic values was significant and the percentage reduction in this case was 21.9%.

from which transverse sections could be cut. After fixation for 2 h at 4 °C with a 3% solution of glutaraldehyde in 0.1 M sodium cacodylate buffer pH 7.4, the nerves were removed and placed in a 2% osmium tetroxide solution in 0.1 M sodium cacodylate buffer pH 7.4 at 4 °C for 1 h. After dehydration and embedding in Epon-Araldite, thin sections were cut for viewing with a Philips 200 electron microscope. The pennate structure of the plantaris muscle made it unsuitable for obtaining a count of the total number of muscle fibres from one transverse section. The EDL muscle, which histological examination had shown to be affected by the disease process, was therefore used as a fast-twitch muscle from which to obtain muscle fibre numbers. The slow-twitch soleus muscle was also studied. Muscles were fixed at their *in vivo* lengths with formol saline (NaCl 0.9%, formaldehyde 4.0%) then removed and treated for 1 h with 10% sulphuric acid to partly separate the fascicles¹⁰. Paraffin wax sections of 7 μ m thick were then cut from the belly of the whole muscle and stained with haematoxylin and eosin. Counting was carried out with the aid of a Leitz Prado microscope slide projector.

Figure 1 shows that rapid early reductions in the numbers of muscle fibres occurred in both soleus and EDL muscles. The percentage reductions in the EDL muscles were somewhat larger than in the soleus muscles and also began a little later. These changes were similar in magnitude to those observed by Rowe and Goldspink³ but, whereas the reduction in the 129ReJ *dy/dy* dystrophic mouse muscles were completed by about 6 weeks of age, those in the C57BL/6J *dy^{2j}/dy^{2j}* dystrophic mice were not completed until about 15 weeks of age. This again raises the question of two allelic genes having different phenotypic expression¹¹. The myelinated axon counts are shown in Fig. 2. In both dystrophic soleus and plantaris nerves the number of myelinated axons was always less than in their normal counterparts at each of the age points studied; these differences were significant. The percentage reduction in the myelinated axons of dystrophic soleus nerves was greater at every age point than the percentage reduction in the dystrophic plantaris nerves. At no age point was the percentage reduction in the nerve to the fast-twitch dystrophic plantaris muscles as great as that reported for the nerve³ to the fast-twitch^{12,13} tibialis anterior muscles. A progressive reduction in the number of myelinated axons also took place in both dystrophic plantaris and soleus nerves such that the 1- and 72-week values for each nerve were statistically significantly different. In addition, the regression coefficients were statistically significantly different from zero while those of normal values were not.

The areas of large unmyelinated axons, previously described in the C57BL/6J *dy^{2j}/dy^{2j}* dystrophic mice¹⁴, were not seen in the distal nerves we studied. We are also not yet able to say whether the myelinated axons that were lost were motor or sensory or both.

We thank Professor Harold Atwood for providing laboratory facilities, and Mrs I. Kwan and Mrs A. Welland for technical assistance. This work was supported by the Muscular Dystrophy Association of Canada.

Cs⁺ causes a voltage-dependent block of inward K currents in resting skeletal muscle fibres

WHEN frog skeletal muscle fibres are bathed in solutions containing Cs⁺ and K⁺ in the ratio 1:4,000, a reduction is observed in the size of inward K currents through the resting membrane. This effect is enhanced by an increase in either hyperpolarisation or external Cs⁺ concentration. It can be predicted from these findings that regenerative changes in membrane potential should be obtainable in fibres, in the presence of Cs⁺, that are hyperpolarised by means of a current electrode. Such responses are described in the last part of this report. In squid axon and frog node^{1,2}, internal Cs⁺ produces a voltage-dependent block of the delayed, outward K currents, though the ratio of Cs⁺ to K⁺ required for this effect is far greater than that used in the experiments reported here. A closer parallel can be drawn between our findings and those recently reported on the inward K currents in the starfish egg cell³.

Sartorius muscles of *Rana temporaria* were equilibrated in isotonic K₂SO₄ Ringer, containing 40 mM K₂SO₄, 8 mM CaSO₄, 1.08 mM Na₂HPO₄, 0.43 mM NaH₂PO₄ and 113 mM sucrose, pH 7.2. Additions of Cs₂SO₄ and K₂SO₄ were made by isotonic replacement of sucrose. Because K⁺ was the only permanent ion in these solutions, the resting potential was identical with the K equilibrium potential, V_K .

Membrane currents were measured using a three-electrode voltage-clamp technique⁴. Because with this method, membrane current is recorded as the potential difference between two intracellular microelectrodes, membrane current is expressed in mV. The membrane potential was held at V_K in all experiments.

Some properties of the resting K conductance are illustrated in Figs 1 and 2. The top of Fig. 1 shows records from two fibres, one (Fig. 1A) in 40 mM K₂SO₄, the other (Fig. 1B) in 40 mM K₂SO₄ plus 1.25 mM Cs₂SO₄. In the absence of Cs⁺ (Fig. 1A), the response to a step-wise hyperpolarisation to a membrane potential of -75 mV (upper record, a) was an inward current which turned on instantaneously and then declined slowly to a steady-state value. When the hyperpolarisation was increased (b), both instantaneous and steady-state currents were larger. The slow decline in K current has been attributed to a depletion of K⁺ adjacent to the membrane⁵. This depletion occurs because about 80% of the resting K conductance is located in the membrane of the transverse tubular system of muscle. During a maintained hyperpolarisation, K⁺ flowing into the sarcoplasm across the tubular wall is replaced partly by other ions from the bulk external medium, resulting in a fall in the tubular K⁺ concentration and consequent shift in V_K (ref. 6).

In the presence of 1.25 mM Cs₂SO₄ (Fig. 1B), both instantaneous and steady-state currents were smaller than for similar hyperpolarising voltages in the absence of Cs⁺. In addition, the current obtained for a large hyperpolarisation to -106 mV (lower record, b) was smaller than that recorded at only -81 mV (a). The ability of Cs⁺ to interfere with the inward movement of K⁺ must increase with hyperpolarisation. It is not clear from these records in Cs⁺ whether the time-dependent decline in current arises from a K depletion, a time-dependent block by Cs⁺, or both.

Mean instantaneous current-voltage relations for a number of fibres in solutions containing 0.01–1.25 mM

Fig. 1 A, records of membrane potential (above) and membrane current (below) from a fibre in 40 mM K₂SO₄ Ringer. Fibre resting potential (RP), -14 mV; holding potential (HP), -14 mV; T, 17.2 °C. B, as (A) except that the solution also contained 1.25 mM Cs₂SO₄. Fibre RP, -15 mV; HP, -15 mV; T, 17.2 °C. Time scale as in (A). C, record of membrane potential (above) and membrane current (below) from a fibre in 95 mM K₂SO₄ Ringer. RP, +3 mV; HP, +3 mV; T, 4 °C. D, as (C) except that the solution also contained 1.25 mM Cs₂SO₄. Fibre RP, +1 mV; HP, +1 mV; T, 3.8 °C. Time scale as in (C). E–F, records were made using the three-electrode voltage-clamp technique, where membrane current is recorded as the potential difference between two impaling microelectrodes, recording membrane potentials V_1 and V_2 , at distances l and $2l$ from the pelvic end of the fibre. The membrane current is then given by the approximation⁴

$$I_m = \frac{a(V_2 - V_1)}{3l^2 R_i} \text{ A cm}^{-2} \quad (1)$$

where a is the fibre radius and R_i is the resistivity of the sarcoplasm. The value of l was 330 μm. The calibration on the current records is in millivolts since the records are of $V_2 - V_1$. If a is assumed to be 40 μm, and R_i to be 180 Ω cm at 17–18 °C and 290 Ω cm at 3–4 °C, 1 mV equals 6.8 μA cm⁻² at 17–18 °C and 4.2 μA cm⁻² at 3–4 °C. E, record of membrane potential (above) and current flowing through an impaling microelectrode (below) made in constant current conditions with two impaling electrodes. The fibre is in a solution containing 40 mM K₂SO₄ and 0.25 mM Cs₂SO₄. Vertical scale: membrane potential (mV). F, records made as in (E), except that the fibre is in a solution containing 40 mM K₂SO₄ and 1.25 mM Cs₂SO₄.

Cs₂SO₄ are given in Fig. 2. In the absence of Cs⁺ (solid curve), the size of the K current depends on the direction in which K⁺ moves across the membrane. When the K-driving force (membrane potential, V_i , minus V_K) is negative, relatively large inward currents can be recorded. In contrast, when V_i minus V_K is positive and the K current is outward, currents are always small. The current-voltage relation is therefore that of an ingoing rectifier⁷.

Addition of Cs⁺ (Fig. 2) did not affect outward K currents. Similarly, when the inward driving force was small, inward currents also resembled those in the control Ringer. As V_i minus V_K was made more negative, however, the inward currents reached a maximum, then declined with further

Fig. 2 Instantaneous current-voltage relations recorded with a three-electrode voltage clamp in muscle fibres. Abscissa, membrane potential, V_m (mV). Ordinate, membrane current, I_m (mV). In the solutions used the membrane current was carried by K^+ . The instantaneous current was obtained by exponential extrapolation of the time-dependent current (Fig. 1A and B) to the beginning of the voltage step. Each experimental point is the mean of results from six to eight fibres. Vertical lines, s.e.m. T , 17–18°C. Fibres were held at the resting potential (which was equal to V_K). RP, -14.13 ± 0.24 mV ($n = 48$) in 40 mM K_2SO_4 , and -13.92 ± 0.37 mV ($n = 24$) in 40 mM K_2SO_4 plus 1.25 mM Cs_2SO_4 (mean $\pm$ s.e.m. of all penetrations, n = no. of observations). Medium was 40 mM K_2SO_4 Ringer plus: Δ , no Cs_2SO_4 ; $\bullet$, 0.01 mM Cs_2SO_4 ; $\circ$, 0.05 mM Cs_2SO_4 ; $\blacksquare$, 0.25 mM Cs_2SO_4 ; $\square$, 1.25 mM Cs_2SO_4 .

hyperpolarisation. It can be concluded from these results that the block of instantaneous K currents by Cs^+ is a function of both the K-driving force and the external Cs^+ concentration.

To test whether the blockage by Cs^+ was purely instantaneous, currents were recorded in fibres in a 95 mM K_2SO_4 Ringer, in the cold. In these conditions the complications introduced by K depletion are much reduced, and the currents show very little time dependence in the control Ringer (Fig. 1C). Nor is there any noticeable time dependence (apart from the initial capacity transient) in the presence of 1.25 mM Cs_2SO_4 (Fig. 1D), which is consistent with the notion that the blockage is instantaneous, and has no time-dependent component.

The measurement of currents at extreme hyperpolarisation is complicated by contractile repriming and membrane breakdown. In solutions containing 40 mM K_2SO_4 plus 0.25 mM Cs_2SO_4 , however, instantaneous currents reached a minimum at -155 mV, then increased gradually with further hyperpolarisation. The current-voltage relation determined in the presence of Cs^+ for membrane potentials between -14 mV and -200 mV can therefore be intercepted at three membrane potentials by a line (drawn parallel to the voltage axis) corresponding to a small inward current. Because two of these potentials will be stable and one unstable, theoretically⁸ it should be possible to record regenerative responses from the unclamped, hyperpolarised membrane.

Muscle fibres were impaled near their mid-points by two electrodes, one to record the membrane potential, and the

other to pass current. When the hyperpolarisation produced by a steady inward current exceeded -115 mV in the presence of 0.25 mM Cs_2SO_4 , the membrane potential developed spontaneous, stable oscillations (Fig. 1E), with distinct thresholds for both a depolarisation and a repolarisation phase, reminiscent of the cardiac action potential. The depolarisation phase of the cycle is probably due to a regenerative increase in K permeability, produced by the potential-dependent dissociation of Cs^+ from the membrane. The potential slowly becomes more negative again as K depletion occurs, until a threshold is reached at which Cs^+ can again bind to the membrane, resulting in a regenerative decrease in K permeability and consequent rehyperpolarisation. That the thresholds and the peak depolarisation do not correspond correctly to predicted points on the current-voltage curve (Fig. 2) is in part due to the difference between the uniform and point methods of membrane polarisation⁸. In addition, the current-voltage relationship varies with time; this is also the reason why the responses are cyclical and not maintained.

Maintained, reversible transitions between two stable potentials (about -75 mV and -140 mV) were produced by brief current pulses superimposed on a steady inward current in 40 mM K_2SO_4 plus 1.25 mM Cs_2SO_4 (Fig. 1F). In these conditions, however, cyclical responses were never seen.

The ability to record two types of regenerative responses in hyperpolarised fibres also supports the conclusion that the blockage of inward currents by Cs^+ depends on both the membrane potential and the Cs^+ concentration. The stability of the responses indicates that the potential-dependent increase in instantaneous current at extreme hyperpolarisations is due to a recovery from Cs^+ blockage, and is not an artefact of membrane breakdown.

Is hyperosmotic neurosecretion from motor nerve endings a calcium-dependent process?

SPONTANEOUS liberation of neurotransmitter quanta is strongly affected by the osmotic pressure of the extracellular fluid. Elevation of the osmolarity by 20–30% increases the rate of release from motor nerve endings by more than one order of magnitude^{1,2}. In this respect the neuromuscular junction resembles some other secretory systems^{3–5}. The mechanism of this hyperosmotic neurosecretion is not yet understood; extracellular calcium ions are not directly responsible, since this effect can be produced in their absence⁶. Recently, it has been suggested that the liberation of neurotransmitter is regulated by the intracellular concentration of free calcium ions^{7–8}. We have therefore examined the hypothesis that hyperosmotic neurosecretion originates from an increase in internal calcium concentration ($[Ca]_{in}$). At the frog neuromuscular synapse however, it is impossible at present to estimate directly free $[Ca]_{in}$; hence we used an indirect technique,

which is based on two assumptions: first, the frequency of the miniature endplate potentials (m.e.p.p.s.) reflects free $[Ca]_{in}$. Second, the movement of calcium ions across the presynaptic membrane is governed by the electrochemical gradient, and by the calcium conductance (g_{Ca}). If hyperosmotic neurosecretion is caused by an increase in $[Ca]_{in}$, then increasing g_{Ca} under reversed electrochemical gradient for the calcium should cause a reduction in the effect of hyperosmotic stress on transmitter release. We report that hyperosmotic neurosecretion is dependent on $[Ca]_{in}$.

The experiments were performed on the sartorius nerve muscle preparation of the frog *Rana pipiens*, using conventional methods for intracellular recording. The standard bathing Ringer solution contained 116 mM NaCl, 2 mM KCl, 1 mM $MgCl_2$ (pH adjusted to 7.0 by titration). The extracellular calcium concentration was either 0.4 mM or less than 10^{-8} M when 1 mM EGTA was added⁹.

Figure 1 illustrates the main experimental observation. A preparation was bathed in a standard Ringer solution with 1 mM EGTA. At A, 50 mM sucrose were added to the medium. This hyperosmotic solution produced a marked increase in the rate of spontaneous transmitter release (miniature end plate potentials frequency). At B, a second perturbation was introduced. The concentration of $[K]_o$ was increased from 2 to 20 mM by iso-osmotic substitution for sodium. This increase in $[K]_o$ is known to produce a depolarisation and an increase in the calcium conductance of nerve membrane¹⁰⁻¹². In normal circumstances, this increase in calcium permeability is expected to cause a calcium influx along the electrochemical gradient for calcium and an increase in transmitter release. At B however, due to the presence of 1 mM EGTA, there is a reversed electrochemical gradient and the increase in calcium permeability presumably causes an efflux of calcium, leading to a decrease in transmitter release. Restoring the inward electrochemical gradient for calcium in C produces a marked increase in m.e.p.p. frequency.

Although extracellular calcium is not necessary to produce hyperosmotic neurosecretion, it has nevertheless an effect on the magnitude of the response. This is illustrated in Fig. 2, where hyperosmotic neurosecretion was induced at A, by adding 50 mM sucrose to standard Ringer solution with 0.4 mM $CaCl_2$. At B the $[Ca]_{out}$

Fig. 1 Hyperosmotic neurosecretion at the frog neuromuscular synapse. A micropipette was placed near the endplate region and the frequency (f) of the spontaneous miniature endplate potentials was monitored at various compositions of the extracellular medium. The control solution contained 116 mM NaCl, 2 mM KCl, 1 mM $MgCl_2$, 1 mM EGTA, with free $[Ca]_o$ of less than 10^{-8} M (with presumably a reversed gradient for calcium ions across the presynaptic membrane). At A the osmolarity of the medium was increased from 225 to 275 mosM, by adding 50 mM sucrose. It is clear that hyperosmotic neurosecretion can be obtained in the virtual absence of calcium ions. At B $[K]_o$ was increased to 20 mM. In contrast to the behaviour in a normal calcium gradient, increase in $[K]_o$ in reversed gradient caused a decrease in f . Restoring an inward calcium gradient in C caused a marked increase in f . Room temperature was approximately 20 °C. The entire experiment was performed at the same fibre, with continuous perfusion of the bathing fluid at an average rate of approximately 2 ml min⁻¹.

Fig. 2 Factors affecting hyperosmotic neurosecretion at the frog neuromuscular junction. The experiment was started in conditions similar to those in Fig. 1, except that the initial $[Ca]_o$ was 0.4 mM (and no EGTA). Hyperosmotic neurosecretion was produced (at A) by 50 mM sucrose. At B $[Ca]_o$ was reduced to less than 10^{-8} M by adding 1 mM EGTA and omitting $CaCl_2$. Comparison of Fig. 1 and Fig. 2 shows that although $[Ca]_o$ is not necessary for hyperosmotic neurosecretion, it nevertheless influences the magnitude of the response; in the absence of $[Ca]_o$ hyperosmotic neurosecretion is reduced to 40–80%. Addition of $[K]_o$ at C caused again a very substantial decrease in m.e.p.p. frequency. In D and E $CaCl_2$ (0.4 mM) was re-introduced and removed respectively, producing the expected changes in f (see text). Room temperature at 20 °C and continuous perfusion with an average rate of approximately 2 ml min⁻¹.

was reduced to less than 10^{-8} M by omitting calcium and adding 1 mM EGTA; this reduced the m.e.p.p. frequency to approximately 50%. Here again a further decrease was obtained by depolarising the membrane by 20 mM KCl (C).

These experiments suggest that hyperosmotic neurosecretion, similar to other processes which modulate transmitter release^{13,14}, depends on changes in $[Ca]_{in}$. The source for the increase in $[Ca]_{in}$ is not yet clear. One possible origin is the mitochondrion¹⁵, since it has been shown that increase in the osmolarity around liver mitochondria inhibits calcium uptake¹⁶.

Sodium and calcium action potential in pituitary cells

SEVERAL endocrine cells or their neoplastic derivatives generate action potentials similar to those seen in neurones¹, and in the adrenal chromaffin cell such regenerative potentials depend primarily on a sodium mechanism^{2–4}. Kidokoro has described action potentials in the GH3 rat pituitary cell line which seem to depend on a calcium mechanism⁵. We have re-investigated the action potential in GH3 cells and found that it results from combined Na and Ca mechanisms in physiological conditions. In addition, we have recorded similar electrical excitability from two human pituitary tumours grown *in vitro*.

GH3 cells, provided through the courtesy of Dr Gordon Sato, were dissociated mechanically and grown in 60-mm plastic tissue culture dishes (Falcon) in Dulbecco's MEM with heat-activated serum (5% foetal calf serum (FCS), 10% horse), penicillin (100 U ml⁻¹) and streptomycin (100 µg ml⁻¹). Human pituitary cells were obtained from surgical specimens of an acidophilic adenoma in an acromegalic 51-year-old woman and of a chromophobe adenoma which recurred after surgery and irradiation in a 53-year-old man without endocrine symptomatology. Pieces of tissue were dissociated mechanically or by treatment with 0.027% trypsin for 2.5 h followed by trituration. Dissociated cells were plated in 35-mm Falcon tissue culture dishes (1–6 × 10⁵ cells per dish) which had been coated with gelatine or a

primary culture of cytosine arabinoside-inhibited non-neuronal rat embryo cells. Human pituitary cells were maintained in McCoy's 5A with 20% FCS or MEM with 10% FCS, 200 mg% glucose and antibiotics.

Cells were penetrated with 3.5 M potassium acetate-filled microelectrodes (40–100 MΩ) under guidance of direct vision by phase contrast microscopic control as described previously⁴, except that self-filling microelectrodes were used sometimes. For recording, the cells were bathed in physiological saline consisting of 150 mM Na, 154 mM Cl, 3.5 mM K, 1.8 mM Ca, 1.0 mM Mg and 2.6 mM phosphate (pH 7.3). Occasionally, 2.5 mM Tris buffer was substituted for phosphate buffer.

In most stable and active penetrated GH3 cells, the resting potential reached between –40 and –67 mV, usually after improving from an initially less negative value. The input resistance also increased substantially to values between 40 and 525 MΩ (mean ± s.e. for 13 active cells of 15 with V_m equal to or more negative than –40 mV, 227 ± 38 MΩ). Stimulation of the cells by an intracellular depolarising pulse produced short duration (duration at half height, 2 ms) action potentials (Fig. 1a–c). These occasionally reached the null potential or showed a small overshoot (Fig. 1a). Multiple action potentials could occur in response to a single prolonged stimulus. In cells of 15 with V_m equal to or more negative than injured by impalement, background hyperpolarisation was usually necessary before stimulation could produce an action potential.

Human pituitary cells maintained in culture appeared as small round or spindle shaped cells (Fig. 2a). Cells from both tumours were able to generate action potentials similar to those seen in GH3 (Fig. 2b).

To determine the ionic basis of the electrical activity, cells were first penetrated in control saline, then in

Fig. 1 Action potentials in GH3 cells. a and b, Control medium, 0.5-ms stimulating pulse at double-headed arrows; c, control medium, 50-ms stimulating pulse; d, Ca-free; e, Mn^{2+} ; f, TTX; g, Na-free; h, Ca-free and TTX; i, Mn^{2+} and TTX. Membrane potentials a–i: 52, 56*, 59, 74*, 80*, 46, 54, 80*, 55 mV. (* is V_m with background hyperpolarising current and is only approximate for (d) and (h) due to bridge imbalance.) Stimulus currents c–i: 0.5, 0.4, 1.3, 0.2, 0.6, 0.6 nA. Calibration bars in (i) are 50 mV and 20 ms in all traces.

Table 1 Results of three sets of experiments

a	Control	Ca-free	Ca-free + TTX	Ca-free
No. of active cells/Total no. of cells	14/15	9/9	0/22	10/12
Resting potential (mean $\pm$ s.e.)	22 ± 3 mV	12 ± 1	17 ± 1	16 ± 2
(range)	(11–50)	(10–15)	(11–37)	(10–35)
b	Control	Mn	Mn + TTX	Mn
No. of active cells/Total no. of cells	6/6	7/10	0/16	13/16
Resting potential	32 ± 7	23 ± 3	24 ± 2	25 ± 2
(range)	(16–55)	(12–41)	(12–42)	(16–38)
c	Control	TTX	TTX + Mn	TTX
No. of active cells/Total no. of cells	10/12	8/14	0/12	7/16
Resting potential	22 ± 3	29 ± 4	26 ± 6	25 ± 4
(range)	(10–40)	(10–70)	(10–66)	(12–56)

solutions which either omitted Ca or Na (after four washes), or contained inhibitors of Na or Ca spike mechanisms (tetrodotoxin (TTX) at 10^{-6} g ml $^{-1}$ to inhibit Na spikes, and Mn $^{2+}$ at 5 mM or Co $^{2+}$ at 7.5 mM to inhibit Ca spikes). Chelating agents were not used. Recordings were then made again in control solution. The proportion of cells with maintained resting potentials equal to or more negative than -10 mV which could generate action potentials was determined. The results of three sets of experiments are shown in Table 1, which includes the mean resting potentials ($\pm$ s.e.) and the range of the resting potentials recorded in each condition.

Fig. 2 Human pituitary cells. *a*, Cultured chromophobe adenoma cells seen with phase contrast microscopy after glutaraldehyde fixation. Calibration bar, 50 μ m. *b*, Action potential in control medium from cell from acidophil adenoma. $V_m = 68$ mV, stimulus current = 0.5 nA. *c*, Action potential in Ca-free medium from cell from chromophobe adenoma. $V_m = 80$ mV, stimulus current = 0.7 nA. Calibration = 20 mV and 10 ms.

When Ca was omitted from the medium, action potentials remained frequent and had rates of rise comparable with those in the control (Fig. 1*d*), in spite of lower resting potentials and input resistances. Action potentials were also demonstrated in the presence of 55 mM Mn $^{2+}$ (Fig. 1*e*). To confirm that the spikes recorded in the absence of Ca or in the presence of Mn $^{2+}$ were Na spikes, TTX was added to the Ca-free and Mn $^{2+}$ media. Activity disappeared within minutes (Fig. 1*h*), but could easily be recovered in both cases once the TTX was washed out (Table 1*a* and *b*).

When TTX was added to control saline (1.8 mM Ca), substantial action potentials were still present (Fig. 1*f*). These had lower maximum rates of rise (15 ± 2 V s $^{-1}$ ($n=6$) compared with 58 ± 7 V s $^{-1}$ ($n=13$) in control (active cells with V_m equal to or more negative than -40 mV in both cases)). Rates of rise were measured from photographic records of swept-out action potentials in cells which had been activated maximally by background hyperpolarisation. When Na was replaced in the medium by equiosmolar Tris, action potentials were still found, but with more difficulty (Fig. 1*g*). Spikes were more readily found when Ca was increased to 10 mM. We believe that the difficulty in Na-free conditions was probably due to nonspecific deterioration of the cells. To confirm that the spikes recorded in TTX were Ca spikes, Mn $^{2+}$ was added to the TTX medium. Action potentials promptly disappeared (Table 1*c*), although slight irregularity occasionally remained in the rising phase of the charging curve (Fig. 1*h*).

These experiments demonstrated that the rising phase of the action potential was generated by both a Na and a Ca

mechanism in physiological ionic conditions. The repolarising phase of the action potential could often be seen to undershoot the resting potential (Fig. 1*b*), and reversed at between -50 and -70 mV. If tetraethylammonium chloride (10 mM), an agent known to inhibit the active post-spike K conductance, was added to the medium, the action potential developed a plateau which could last up to 300 ms before repolarisation. It is likely, as in other excitable cells, that the rapid repolarisation of the membrane which terminates the spike is due to an increased K conductance.

The human pituitary tumour studies were limited by the small amounts of tissue in surgical specimens. The cells remained electrically excitable in Ca-free medium (Fig. 2*c*), and in the presence of Co $^{2+}$ (in the one tumour so studied), indicating that a large part of the spike was probably due to Na. The recordings in TTX, however, did not enable us to make a definite statement about the presence or absence of a major Ca component of the spike.

It has been established in various neuronal and endocrine tissues that output of transmitter or hormone is coupled with influx of Ca (ref. 6). In this regard it would seem useful for endocrine cells to utilise Ca-spike mechanisms to enhance excitation-secretion coupling. There is evidence for large Ca-spikes in GH3 cells and pancreatic B cells ^{7,8} but not in adrenal medulla ^{2,3} , pheochromocytoma or bronchial carcinoids ^{1} . In those endocrine cells without large Ca spikes it is likely that Ca entry could occur during depolarisation due to ACh (adrenal medulla) or other stimulatory agents, or during the Na action potential ^{1,9} . The function of Na action potentials in cells with large Ca spikes is less clear. They could help to spread excitation among electrically coupled cells, or they could act in some way as modulators of the Ca mechanism.

The data presented here apply to neoplastic derivatives of anterior pituitary cells. Action potentials have not been reported in normal anterior pituitary cells, but Davis and Hadley ^{10} have recorded extracellular spikes from cells in the pars intermedia of the frog. Preliminary recordings from unidentified rat and gerbil anterior pituitary cells *in vitro* in our laboratory have demonstrated action potentials. The detailed physiology of these responses is yet to be determined.

Caffeine restores feeding response to 2-deoxy-D-glucose in 6-hydroxydopamine-treated rats

A LARGE portion of the central catecholaminergic nerve terminals of the rat are destroyed by administering 6-hydroxydopamine (6-HDA) via the cerebrospinal fluid¹⁻³. Animals lesioned in this way often appear normal, yet show many subtle behavioural abnormalities⁴. We have been examining one example of this phenomenon, the failure of 6-HDA-lesioned rats to increase food intake when given a systemic injection of 2-deoxy-D-glucose (2-DG) (refs 5, 6). This glucose analogue seems to elicit feeding in intact rats due to its inhibition of glycolysis in cerebral chemoreceptor cells^{7,8}. We have proposed⁹ that lesioned animals do not eat because of an insufficient central catecholaminergic response to the severe decrease in glucose utilisation induced by 2-DG (ref. 10). If so, then pretreatments which serve to augment this neurochemical response might be expected to reinstate behavioural function. Consistent with this hypothesis, very large increases in telencephalic tyrosine hydroxylase activity in 6-HDA-lesioned animals, which occur following chronic insulin treatment, are associated with the restoration of 2-DG-induced feeding¹¹. Many of the physiological effects of catecholamines in the sympathetic nervous system seem to be mediated by an increase in the cyclic AMP concentration of the target cells. Methylxanthenes, such as caffeine and theophylline, inhibit phosphodiesterase, prevent cyclic AMP degradation, and thereby potentiate the catecholamine-stimulated rise in cyclic nucleotide^{12,13}. They also enhance many of the behavioural and physiological effects of catecholamines¹²⁻¹⁵, presumably by the same mechanism. We therefore sought to determine whether the acute administration of those sympathomimetic agents, in intact and 6-HDA-lesioned rats, also would potentiate 2-DG-induced feeding, a behaviour that seems to be mediated, in part, by central catecholaminergic neurons. We report that caffeine restores the 2-DG-induced feeding response.

Male albino Sprague-Dawley rats (Zivic-Miller), weighing 250-300 g at the beginning of each experiment, were housed in individual wire mesh cages and allowed free access to

Table 1 Effect of caffeine and 2-DG on food intake

2-DG dose (mg per kg body weight)	n	Food intake above baseline (g)	
		No caffeine	Caffeine
0	6	-0.9±0.5	0.0±0.4
185	5	+2.2±0.9	+5.1±0.5
375	5	+3.2±0.8	+5.2±0.8
750	5	+3.6±0.5	+7.2±1.4

Food intake was measured every hour for 5 h (9.30 a.m. until 2.30 p.m.) on each of two successive days. On day 3, after the first hour of testing, each rat was injected i.p. with isotonic saline or 2-DG. Animals given 2-DG consumed significantly more food (mean±s.e.) during the following 4 h than they had on previous days ($P < 0.01$ in each case). One week later, the rats were tested as before, except that on day 3 they were given caffeine (50 mg per kg, i.p.) along with saline or 2-DG. Rats given 2-DG consumed even more food than they had when 2-DG alone was given ($P < 0.05$ in each case).

Table 2 Effect of xanthenes on 2-DG-induced feeding

Xanthene dose (mg per kg body weight)	n	Food intake (g)	
		Baseline	2-DG + xanthene
None	5	1.3±0.5	3.8±0.7
Caffeine			
12.5	5	0.8±0.3	5.9±0.7
25.0	5	0.9±0.5	6.9±0.5
50.0	5	1.0±0.5	6.3±1.1
100.0	3	0.9±0.5	1.5±0.4
Theophylline			
12.5	5	1.3±0.5	6.9±0.4

Food intake (mean±s.e.) was determined according to the protocol described in Table 1, except that the dose of 2-DG was held constant (375 mg per kg, i.p.) and either the dose of caffeine was varied or theophylline was given instead. All but the highest dose of caffeine increased food intake significantly more than when 2-DG alone was given ($P < 0.01$ in each case).

Purina Lab Chow pellets and tap water. In the first series of experiments animals were given 2-DG, either caffeine or theophylline, or a combination of 2-DG and a xanthene. 2-DG added alone produced a dose-dependent increase in food intake (Table 1). Neither caffeine nor theophylline affected food intake when given alone, but both significantly enhanced the feeding response to 2-DG (Tables 1 and 2).

In the second series of experiments, we administered 6-HDA (200 µg in 20 µl) or its vehicle (0.9% NaCl, 0.1% ascorbic acid) by way of the lateral ventricle 30 min after an intraperitoneal (i.p.) injection of desmethylinipramine (25 mg per kg body weight). We have previously found this treatment to produce a permanent 90-95% depletion of telencephalic dopamine, without altering brain noradrenaline content⁶. Two to three weeks after the lesion was produced, the effects on food intake of optimal doses of 2-DG (375 mg per kg, i.p.) and caffeine (25 mg per kg, i.p.) were determined.

Table 3 Effect of caffeine and 2-DG on food intake in intact and 6-HDA-lesioned rats

	Food intake (g)	
	Intact	6-HDA
Baseline	1.1±0.3	1.1±0.4
2-DG	4.4±1.3	0.7±0.4
2-DG + caffeine	7.7±0.6	7.2±1.0

Food intake (mean±s.e.) was determined according to the protocol described in Table 1, except that a single dose of 2-DG (375 mg per kg, i.p.) was given with caffeine (25 mg per kg, i.p.). Intact rats ($n = 7$) ate more when 2-DG was given with or without caffeine ($P < 0.05$ and < 0.001 , respectively), whereas 6-HDA-lesioned rats ($n = 7$) only ate more when 2-DG was given with caffeine ($P < 0.001$).

Vehicle-treated rats increased food intake in response to 2-DG, and ate even more when caffeine was also administered (Table 3). As expected, 6-HDA-lesioned rats did not increase their food intake after 2-DG treatment alone. When 2-DG was administered together with caffeine, however, the lesioned rats ate significantly more food than before, almost as much as controls did in response to the same treatment (Table 3).

There are several possible explanations for the effects of caffeine on 2-DG-induced feeding in control and lesioned animals. First, caffeine may have altered the effectiveness of 2-DG as a competitive inhibitor by somehow reducing the concentration of circulating glucose. This is apparently not the case, however, since caffeine, if anything, increased the normal hyperglycaemic response to 2-DG (Table 4). Second, because of the ubiquitous involvement of cyclic AMP as a 'second messenger', caffeine may be acting by potentiating the effects of some hormone or transmitter other than brain catecholamines. While the present data do not rule out this possibility, there is a good reason to

believe that 2-DG-induced feeding is mediated in part by the release of central amines since it can be blocked both by the selective destruction of catecholaminergic terminals^{5,6,16} and by AMT (ref. 16), an inhibitor of catecholamine biosynthesis. Third, and most likely, caffeine may produce a net increase in the activation of target cells by catecholamines. This may occur either by potentiating the effects of catecholamines on cyclic AMP levels or by increasing catecholamine release, another known property of methylxanthenes¹⁷. Experiments to further elucidate the mechanisms of this phenomenon are in progress.

Table 4 Effect of caffeine and 2-DG on blood glucose concentration

2-DG dose (mg per kg body weight)	Blood glucose concentration (mg per 100 ml)	
	No caffeine	Caffeine
0	114 ± 5	124 ± 7
185	153 ± 15	201 ± 7
375	274 ± 16	288 ± 14

Blood glucose concentration (mean ± s.e.) in rats after 0 or 25 mg per kg caffeine was given i.p. along with isotonic saline or 2-DG. Food was withheld for 1 h, after which rats were killed by decapitation. From blood samples obtained when rats were killed, glucose was determined colorimetrically following its reaction with glucose oxidase (Worthington) ($n = 4$ or 5 in each group). Statistically significant effects of caffeine were observed only when 185 mg per kg 2-DG had been administered ($P < 0.05$).

Our data are consistent with the hypothesis that 6-HDA-lesioned rats fail to respond behaviourally to 2-DG because of an inadequate activation of central catecholamine receptors. Previously, we also have found that amphetamine will stimulate feeding in anorexic 6-HDA-treated rats⁴, and comparable results have been obtained by others^{18,19}. It is of interest that caffeine and amphetamine both have been used in the treatment of such seemingly diverse syndromes as narcolepsy²⁰ and hyperkinesis^{21,22}. The ability of the sympathomimetic drugs to restore function following damage to central catecholaminergic systems suggests that similar damage may be present in these clinical disorders^{23,24}.

Nucleic acid sequences of primate type C viruses in normal and neoplastic human tissues

RECENT reports on the isolation of type C viruses from human cells have generated considerable controversy because of the close relationship of the viruses to the type C viruses of subhuman primates^{1–5}. These findings have been interpreted as evidence for contamination despite the repeated isolation of some type C viruses from separate clinical specimens or from separate frozen primary cell stocks of the same donor^{6–9}. Our laboratory has described a type C virus which is released from the HEL-12 strain of normal human embryonic lung fibroblasts⁵. The HEL-12 virus is related immunologically to simian sarcoma (woolly monkey fibrosarcoma) virus (SiSV) and the endogenous type C viruses of baboons and domestic cats^{9–11}. To demonstrate that the HEL-12 virus is not an adventitious contaminant, fresh human tissues were examined for antigenic cross-reactivity with HEL-12 virus antigens. Some patients with myelogenous leukemia contain circulating immunoglobulins which specifically inhibit the reverse transcriptases of HEL-12 virus and primate type C viruses¹². In addition, the glomerular immune complexes in patients with systemic lupus erythematosus contain antigens related to HEL-12 virus proteins¹³. Using the techniques of molecular hybridisation, we demonstrate here that HEL-12 cells contain proviral DNA sequences before antigen expression or spontaneous virus release can be detected. We also present evidence for the existence of nucleic acid sequences homologous to HEL-12 viral RNA in the DNAs from certain cancer patients.

HEL-12 cultures were grown from frozen primary cell stocks⁵. Type C viral antigens or extracellular virus were not detected during the first 20–40 d, but the cultures gradually expressed cytoplasmic viral antigens and released type C particles between 80 and 120 d. DNA was extracted from early-passage (36 d of culture) HEL-12 cells in which type C viral antigens were not detected by indirect immunofluorescence or from late-passage (115 d of culture) HEL-12 cells which spontaneously released type C virus^{9,14}. The DNA was sheared, denatured and reannealed in the presence of trace amounts ¹²⁵I-HEL-12 viral RNA. Aliquots were evaluated for duplex formation at various times thereafter by observing resistance to pancreatic RNase digestion in conditions of high ionic strength. Both early-passage and late-passage HEL-12 cells contained DNA sequences homologous to HEL-12 viral RNA (Fig. 1). The relative displacement of the curves along the abscissa suggested that early-passage cells contained fewer copies of the viral genome than late-passage cells. The ¹²⁵I-HEL-12 RNA also hybridised to DNA from a marmoset fibroblast line infected with SiSV (71AP1/SiSV), thereby confirming the relatedness of HEL-12 virus to SiSV⁵. The ¹²⁵I-HEL-12 viral RNA probe eventually hybridised to a similar extent with DNA from early-passage and late-passage HEL-12 cells and 71AP1/SiSV cells. Some differences were noted between the t_m values of the hybrids formed with HEL-12 viral DNAs and 71AP1/SiSV-DNA, suggesting that the proviral sequences being detected were not identical in all cases (Fig. 1, Table 1). Since HEL-12 cell cultures express antigens related to SiSV and baboon endogenous virus (BaEV)^{9,14}, HEL-12 viral RNA was hybridised to DNA extracted from a bat lung cell line productively infected with BaEV. The stock of HEL-12 viral RNA used for these experiments lacked detectable BaEV sequences (Table 1), possibly because the HEL-12 cell cultures released virions with SiSV in great excess. Moreover, we have observed intervals in the lifespan of HEL-12 cells during

(Grade T-2, Collaborative Research) was added. The mixture was stirred at room temperature for 16 h. The oligo(dT)-cellulose was removed and packed into a Pasteur pipette which was washed exhaustively with $2 \times \text{SSC}$. The poly(A)-containing HEL-12 viral RNA was eluted by successive washes of the column with 10 mM Tris-HCl, pH 7.2. The eluate was adjusted to a final NaCl concentration of 0.25 M in order to stabilise the RNA. Iodination was performed as originally described by Commerford¹⁸ and modified by Prenskey *et al.*¹⁰. The specific activity of the ^{125}I -RNA was approximately $5\text{--}10 \times 10^7$ c.p.m. per μg . Hybridisations were carried out in sealed glass capillary tubes with approximately 1,000 c.p.m. of ^{125}I -viral RNA in 0.4 Na-phosphate, pH 6.8. The DNA-RNA ratio in all cases was at least 5×10^6 . Each reaction mixture was placed in boiling water for 10 min and subsequently incubated at 60°C . Hybrids were evaluated at progressively greater C_0t values²⁰ by determining resistance to $20 \mu\text{g ml}^{-1}$ pancreatic RNase (Worthington) at high ionic strength ($2 \times \text{SSC}$) for 2 h at 37°C . Less than 3% of the ^{125}I -viral RNA was resistant to RNase when incubated in the absence of DNA or when incubated to $C_0t = 4 \times 10^4$ with calf thymus DNA. This resistant fraction was subtracted from all values. The C_0t values shown are uncorrected for $[\text{Na}^+]$ ion concentration. The final extent of hybridisation is plotted relative to an absolute value of 43% obtained using 71API/SiSV DNA. Inset, thermal stabilities of ^{125}I -RNA:DNA hybrids. ^{125}I -HEL-12 viral RNA and DNAs from various sources were annealed to a C_0t of $10^4\text{--}2 \times 10^4$ and diluted into 50–100 volumes of $1 \times \text{SSC}$ buffer. Aliquots were held at the indicated temperatures for 10 min, adjusted to a final concentration of $2 \times \text{SSC}$ buffer and digested with $20 \mu\text{g ml}^{-1}$ pancreatic RNase for 2 h at 37°C . Sources of DNAs: Δ , marmoset fibroblast cells releasing SiSV (71API/SiSV); $\circ$, HEL-12 cells passaged for 36 d; $\bullet$, HEL-12 cells passaged for 115 d; $\blacktriangle$, calf thymus DNA.

which only SiSV-related antigens are expressed¹⁴. The absence of BaEV-RNA in this stock of HEL-12 virus has been confirmed by R. G. Smith and R. C. Gallo (personal communication).

Two of 14 DNA samples from nine cancer patients likewise contained DNA sequences hybridisable to the RNA of HEL-12 virus (Fig. 2). In one case, proviral sequences were detected in the spleen of an 11-yr old boy who died from an osteogenic sarcoma. This tumour uncommonly metastasises to the spleen²¹, and no evidence for splenic metastases was obtained by histological post-mortem examination. The results with DNAs from other tissues of this patient were interesting because HEL-12 proviral sequences were not detected in the primary tumour from the femur

or in the patient's liver (Fig. 2). A second case involved the spleen of an adult with acute myelogenous leukaemia. Proviral DNA sequences were found in the spleen although to a lesser extent than in early-passage or late-passage HEL-12 cells or in the spleen of the boy with osteogenic sarcoma (Fig. 2). The thermal stabilities of these hybrids were not appreciably different from those of the ^{125}I -RNA:HEL-12 DNA hybrids (Fig. 2, Table 1).

The results (Table 1) can be summarised as follows: (1) DNA extracted from early-passage HEL-12 cells contain proviral sequences. (2) With continued *in vitro* propagation, HEL-12 cells acquire an increased complement of proviral sequences, possibly as the result of a selective proliferation of a cell fraction containing the HEL-12 viral genome or

Table 1 HEL-12 proviral sequences in various DNAs

Diagnosis	Source of DNA	Final relative % hybridisation of ^{125}I -HEL-12 viral RNA	Hybrid t_m ($^\circ\text{C}$)	Δt_m ($^\circ\text{C}$)
—	71API/SiSV	100	77	8.0
—	HEL-12 cells, early-passage	95	82.5	2.5
—	HEL-12 cells, late-passage	93	82.0	3.0
Osteogenic Sarcoma	Spleen	90	84.5	0.5
	Liver	1	—	—

The actual % hybridisation of 71API/SiSV DNA was 43. The Δt_m ($^\circ\text{C}$) is expressed relative to a t_m of 85.0°C for ^{125}I -HEL-12 viral RNA: AML spleen DNA hybrid. AML, acute myelogenous leukaemia; ALL, acute lymphatic leukaemia; BL88/BaEV, bat lung cells infected with BaEV from *Papio anubis*. All DNAs were annealed with ^{125}I -HEL-12 viral RNA to a $C_0t \geq 10^4$.

from a low level of virus spread from cell to cell in early-passage cultures. Embryonic tissues were not available to demonstrate proviral sequences in the original lung tissue from which the HEL-12 cell strain was established in 1974. Even if available, proviral sequences might not be found if present in a small number of cells of such heterogeneous tissues. (3) DNA sequences homologous to HEL-12 viral RNA have also been detected in the spleen DNA of a boy with osteogenic sarcoma, and to a lesser extent, in the spleen of an adult with acute myelogenous leukaemia. The proviral sequences in the DNAs of HEL-12 cells and fresh human tissues were related to SiSV as evidenced by the ability of the ^{125}I -HEL-12 viral RNA to hybridise to 71AP1/SiSV DNA. Thermal denaturation profiles of these hybrids, however, reveal some differences between the hybrids formed between HEL-12 viral RNA and DNA from cells producing HEL-12 virus or SiSV. This suggests

Fig. 2 Hybridisation of ^{125}I -HEL-12 viral RNA to DNAs from organs of cancer patients. The conditions for purification and shearing of DNAs were as described in Fig. 1. The final extent of hybridisation is plotted relative to that obtained with 71AP1/SiSV DNA. Source of DNAs: Δ , 71AP1/SiSV (from Fig. 1); $\bullet$, spleen, and $\square$, liver from patient with osteogenic sarcoma; $\circ$, primary osteogenic sarcoma; $\blacksquare$, spleen and $\square$, liver from patient with acute myelogenous leukaemia. Inset, thermal stabilities of hybrids in $1\times\text{SSC}$ buffer.

that the proviral sequences in HEL-12 cells and fresh human tissues may not be identical to those detected in 71AP1/SiSV cells. The presence of proviral sequences in early-passage HEL-12 cells argues against the notion that the HEL-12 virus is a laboratory contaminant, especially since primate type C viruses have not been propagated by us³. But, by far the strongest argument against adventitious contamination seems to be the presence of SiSV-related sequences in fresh autopsy tissues of patients with malignancies.

We thank R. C. Gallo, D. H. Gillespie, S. Panem and R. G. Smith for helpful discussions, W. Prenskey for a gift of iodinated RNA and M. Reitz for DNA of 71AP1/SiSV. This work was supported by the US NCI. E. V. P. is supported by the National Institute of General Medical Sciences.

Chaos in an enzyme reaction

DYNAMIC systems are usually thought to have either monotonic or periodic behaviour. Although the possibility of other types of behaviour has been recognised for many years, the existence of non-monotonic, non-periodic behaviour in dynamic systems has been firmly established only recently. It is termed chaotic behaviour. A review on the rapidly expanding literature on chaos in discrete model systems described by difference equations has been published by May¹. Rössler², on the other hand, has discussed a few published works on systems of differential equations with chaotic solutions, and he has proposed a three-component chemical model system which he argues has chaotic

Fig. 1 Oscillations in oxygen concentration in peroxidase catalysed oxidation of NADH in system open to O_2 . A stirred 5 ml sample containing horseradish peroxidase, 10 μM 2,4-dichlorophenol and 0.2 μM methylene blue in a 0.1 M Na-acetate buffer pH 5.1 was in contact with an O_2/N_2 gas mixture at atmospheric pressure containing 1.9 volume % O_2 . A solution of 0.2 M NADH was pumped into the sample at 11 μl per h. The oxygen concentration in the liquid was measured with a Clark electrode. The temperature was 28 $^\circ\text{C}$. The concentration of peroxidase was a, 0.90 μM ; b, 0.55 μM and c, 0.45 μM .

Fig. 2 a, Amplitudes ($A(n+1)$) plotted against preceding amplitudes ($A(n)$) from Fig. 1b. b, Periods ($P(n+1)$) plotted against preceding periods ($P(n)$) from Fig. 1b. Trajectories with arrows were drawn to show that the transition functions allow the period 3.

solutions. The argument is based on a theorem by Li and Yorke³. Here we report the finding of chaotic behaviour as an experimental result in an enzyme system (peroxidase). Like Rössler² we base our identification of chaos on the theorem by Li and Yorke³.

When the oxidation of NADH by O_2 , catalysed by horse-radish peroxidase, takes place in a stirred solution where O_2 can enter by diffusion from the gas phase, oscillations^{4,5} and bistability⁶ may be observed in the reaction system. Sustained oscillations may be achieved by continuously supplying NADH to the reaction mixture. In the present experiments this was done by pumping in an NADH solution at a slow constant rate. The wave form of the oscillation depended on the enzyme concentration as shown in Fig. 1. In Fig. 1b there is no apparent periodicity. This irregular oscillation was analysed by plotting each amplitude against the preceding amplitude as described by Lorenz⁷. This plot (Fig. 2a) reveals that the amplitudes found in our experiment satisfy a well defined cap-shaped transition function. When the durations of the periods are plotted in the same way a similar transition function is found (Fig. 2b). A random distribution of points in the plane would have been expected if the irregularities in the oscillation were caused by random perturbations.

The existence of the cap-shaped transition function indicates that the system has either a periodic behaviour with a complicated period or it has chaotic behaviour. The two possibilities can be distinguished using the theorem of Li and Yorke³ which states that if the transition function allows the period three it allows any period and chaos exists. In Fig. 2a and b it is seen that it is possible to design trajectories of three transitions which will bring the system back beyond the origin. Thus our system exhibits chaotic behaviour in the Li and Yorke sense. We are not aware of any other examples of chaos in chemical reaction systems.

Specific inhibition of chromatin-associated poly(A) synthesis *in vitro* by cordycepin 5'-triphosphate

It has been established that many eukaryotic mRNAs contain poly(adenylic acid) tracts at their 3'-termini. The polyadenylation of mRNA occurs post-transcriptionally in the nucleus as a rapid, initial addition of 100–200 adenylate residues to the pre-mRNA (ref. 1). Subsequently, a slower chain extension (6–8 bases) of the poly(A) tail seems to occur both in the nucleus and in the cytoplasm². The initial polyadenylation reaction can be specifically inhibited by the drug cordycepin (3'-deoxyadenosine) in cell culture, presumably by its conversion to the triphosphate analogue which acts as a competitive inhibitor of poly(A) polymerase. Cordycepin, however, has little effect on the slower poly(A) extension reaction³ or on the formation of mRNA precursor molecules^{4–6}; but it can inhibit rRNA synthesis⁷. Contrary to the *in vitro* observations, cordycepin 5'-triphosphate (3'dATP) is not a specific inhibitor of poly(A) synthesis *in vivo*, relative to RNA synthesis^{8,9}, and RNA polymerase I (which synthesises rRNA) is actually less sensitive to inhibition by 3'dATP than RNA polymerase II (ref. 10) (which is presumed to be involved in the synthesis of mRNA). Since nuclear poly(A) polymerase occurs in two functional states as 'free' and 'chromatin-bound' forms¹¹, we reasoned that if the chromatin-associated poly(A) polymerase were involved in the initial polyadenylation of mRNA, it might be selectively inhibited by 3'dATP. The present studies, designed to test such an idea, demonstrate that, as *in vivo*, the initial polyadenylation reaction can be selectively inhibited *in vitro* by low levels of 3'dATP. These data also show that higher levels of 3'dATP can inhibit RNA synthesis, 'chromatin-bound' RNA polymerase I activity being significantly more sensitive than the 'bound' RNA polymerase II activity.

Initial studies measuring the effect of 3'dATP on poly(A) synthesis catalysed by 'bound' and 'free' poly(A) polymerases in whole nuclei, indicated that the 'bound' enzyme was 100–200 times more sensitive than the 'free' poly(A) polymerase. To study the inhibition by 3'dATP in more detail, we separated the poly(A)-synthesising activities of isolated nuclei by preparing a nuclear sap fraction and chromatin from the nuclear residue to yield the 'free' and 'bound' enzymes, respectively. The effect of increasing concentrations of 3'dATP on poly(A) synthesis catalysed by the 'free' and by the 'bound' enzyme is shown in Fig. 1a. Approximately 150 $\mu\text{g ml}^{-1}$ of drug were needed to achieve 50% inhibition of the 'free' enzyme, whereas the same inhibition was attained with less than 1 $\mu\text{g ml}^{-1}$ of 3'dATP

Fig. 1 Effect of 3'dATP (a) and 2'dATP (b) on 'free' and 'bound' poly(A) polymerases. Rat liver nuclei were prepared by homogenisation of the tissue in hypertonic sucrose (2.3 M) (ref. 15) and the isolated nuclei were gently resuspended in hypotonic buffer essentially as described previously¹¹. After centrifugation (40,000g; 30 min) to remove the nuclei, glycerol was added to the supernatant fraction so that the final concentration was 20% (v/v). This nuclear supernatant fraction was the source of the 'free' poly(A) polymerase. Chromatin was prepared from the nuclear pellet after washing with the same hypotonic buffer. Isolation of chromatin was as described previously¹⁶ except that the Triton X-100 and NaCl washes were omitted. The final chromatin pellet was resuspended in 0.4 mM Tris-HCl (pH 8) (0.5 ml per g liver) and used within 36 h of preparation. The DNA content of nuclei and chromatin was estimated as described by Burton¹⁷. Poly(A) polymerase activity was assayed in a reaction mixture containing 38 mM Tris-HCl (pH 8), 38 mM KCl, 0.7 mM MnCl₂, 1.0 mg per ml phosphoenolpyruvate, 2 μg per ml pyruvate kinase, 0.37 mM ³H-ATP (2,000 c.p.m. nmol⁻¹), addition of 3'dATP or 2'dATP as indicated and appropriate amounts of poly(A) polymerase in a total volume of 120 μl. For analysis of 'free' poly(A) polymerase, poly(A) was included at a concentration of 375 μg ml⁻¹. After 1 h at 37 °C, the reaction was terminated by addition of excess ATP (10 μl of ATP, 10 mg ml⁻¹). Aliquots of 110 μl were spotted on to DE81 filters and processed as described previously¹⁵. All assays were performed in quadruplicate; zero time backgrounds were less than 150 c.p.m. ○, 'Free' poly(A) polymerase obtained from nuclei representing 45 μg DNA; ●, chromatin representing 50 μg (---) or 160 μg (—) DNA. Horizontal bars indicate s.e.m.

when 'bound' poly(A) polymerase was derived from an equivalent amount of tissue. Since the activity catalysed by the chromatin-associated enzyme represents only a small percentage of the activity of the 'free' poly(A) polymerase, we also measured the effect of 3'dATP when the levels of chromatin and nuclear supernatant (sap) fractions were adjusted to give the same activity. When the activities were so adjusted, the 'bound' enzyme was still 75 times more sensitive than the 'free' enzyme.

In order to further substantiate the specific inhibitory effect of 3'dATP on chromatin-associated poly(A) polymerase relative to 'free' enzyme, the effect of 2'dATP, the naturally occurring deoxynucleotide, was measured. 2'dATP

did not specifically inhibit chromatin-bound poly(A) synthesis (Fig. 1b); in fact, 'free' poly(A) polymerase was slightly more sensitive to inhibition by 2'dATP than the 'bound' enzyme. Interestingly, inhibition of 'free' poly(A) polymerase by 2'dATP was greater than that obtained with 3'dATP, 50% inhibition occurring at 70 and 120 μg ml⁻¹, respectively.

Since 3'dATP is an ATP analogue, the relationship of the inhibitor to substrate levels was investigated. Figure 2 shows the double reciprocal plots of velocity against ATP concentration in the presence and absence of 3'dATP. The inhibition of the 'free' poly(A) polymerase by 3'dATP was competitive with substrate (b). The K_m and K_i calculated from Fig. 2b were 62 μM and 40 μM, respectively. When the relationship of 3'dATP to ATP levels was investigated using the chromatin fraction, a non-competitive relationship was observed (Fig. 2a). The calculated K_m and K_i were 100 μM and 1.3 μM, respectively. Although the K_m values of the two enzyme activities were similar, the K_i for chromatin-associated poly(A) synthesis was much lower, indicating that this reaction was at least 30 times more sensitive to inhibition by 3'dATP than poly(A) synthesis by the 'free' enzyme. Inhibition of poly(A) polymerase for both the 'free'

Fig. 2 Effect of 3'dATP on the double reciprocal plot of velocity against substrate concentration for 'bound' and 'free' poly(A) polymerases. Chromatin and nuclear supernatant fractions were prepared and assayed as described in Fig. 1 in the presence (▲) and absence (●) of 3'dATP at varying ³H-ATP⁻¹ levels. a, Chromatin equivalent to 60 μg DNA and 3'dATP at a concentration of 4 μM were used; b, 'free' poly(A) polymerase was derived from 90 μg nuclear DNA and 3'dATP was at a concentration of 118 μM. The ATP concentration in the assay ranged from 7–235 μM with specific activities ranging from 2 × 10⁵ to 7 × 10⁵ c.p.m. nmol⁻¹. Lines were fitted by least squares analysis.

Fig. 3 Effect of 3'dATP on chromatin-bound RNA polymerases. RNA synthesis was measured in an assay similar to that described in Fig. 1 except that CTP, GTP and ^3H -UTP (30 c.p.m. pmol $^{-1}$) were included at a concentration of 50 μM . Chromatin equivalent to 60 μg DNA was used. Reactions were incubated for 5 min at 30 °C, after which excess UTP was added and filters processed as described previously¹⁵. Reactions were performed in quadruplicate; zero times backgrounds were less than 100 c.p.m. Analyses were performed in the presence and absence of α -amanitin. The decrease in activity when 1 $\mu\text{g ml}^{-1}$ α -amanitin was included represented RNA polymerase II. Activity in the presence of α -amanitin represented primarily RNA polymerase I since high levels of toxin (150 $\mu\text{g ml}^{-1}$) produced only 10–15% decrease in activity (indicating little RNA polymerase III contamination). Δ , RNA polymerase II, 100% activity corresponded to 22.8 ± 1.8 pmol UMP incorporated in 5 min; $\blacktriangle$, RNA polymerase I, 100% activity corresponded to 13.2 ± 0.8 pmol UMP incorporated in 5 min.

and 'bound' forms by 2'dATP was competitive with ATP levels, so it seems that not only is 3'dATP a specific inhibitor of chromatin-associated poly(A) synthesis, but that its mode of action differs from inhibition of the 'free' form of enzyme.

We then measured the effect of 3'dATP on RNA polymerase activity associated with the chromatin fraction, maintaining the assay conditions as close as possible to those for poly(A) synthesis to avoid unnecessary artefacts. Figure 3 shows the inhibition of chromatin-associated RNA polymerases I and II by 3'dATP. It can be seen that polymerase I was more sensitive to the inhibitor than polymerase II. At 60 $\mu\text{g ml}^{-1}$ 3'dATP, which inhibited polymerase I activity by 70%, polymerase II activity was inhibited only by 5%. Although the 'bound' polymerase I activity was reduced by 3'dATP, this inhibition was far less than observed for 'bound' poly(A) polymerase activity, where 50% inhibition could be achieved at concentrations of less than 1 $\mu\text{g ml}^{-1}$ using a similar amount of chromatin. RNA polymerase activity can also be detected in the nuclear supernatant fraction¹². As previously reported for partially purified enzymes^{8,10}, 3'dATP had a similar effect on 'free' RNA polymerases present in the nuclear supernatant fraction, with a dose-response curve similar to that for chromatin-bound RNA polymerase I (data not shown).

The marked sensitivity of chromatin-associated poly(A) polymerase, the lack of inhibition of RNA polymerase II in the same subnuclear fraction and the intermediate sensitivity of chromatin-bound RNA polymerase I by 3'dATP are results similar to those obtained *in vivo* by cordycepin. The lack of differential inhibition of 'free' poly(A) polymerase relative to 'free' RNA polymerases by 3'dATP supports the observations made using partially purified enzymes. Thus, although purified enzymes are invaluable in determining reaction characteristics, data obtained from such systems

should be interpreted with caution. In this case, inhibition of partially purified enzymes by 3'dATP, probably reflects the effects of the drug on extrachromosomal events. The selectivity of inhibition of chromatin-associated poly(A) synthesis by 3'dATP is further evident when a comparison is made with the effect of the compound on polyadenylation of endogenous RNA in isolated mitochondria, where chromatin factors are not present. Inhibition of the mitochondrial polyadenylation reaction occurs only at relatively high concentrations of 3'dATP (ref. 13) (50% inhibition occurring at 300 μM , a value even greater than the K_m). The lack of inhibition of mitochondrial polyadenylation at this concentration of 3'dATP agrees well with the relative insensitivity of mitochondrial polyadenylation to cordycepin *in vivo*¹⁸.

The remarkable sensitivity of chromatin-associated poly(A) polymerase to cordycepin triphosphate, the close association of this activity with DNA and the similar inhibition responses of the initial polyadenylation reaction *in vivo* and 'bound' enzyme activity *in vitro*, all tend to indicate that the latter activity indeed represents the initial polyadenylation reaction. The 'free' poly(A) polymerase activity, by virtue of its localisation in the nuclear supernatant and cytosol fractions¹⁴, coupled with its relative insensitivity to low levels of 3'dATP, should represent the enzyme activity responsible for the additional polyadenylation reaction. These studies have thus provided a simple system to differentiate between initial polyadenylation and subsequent chain extension reactions *in vitro*.

The complete **Index** for 1976 is available, price £2.50. Copies of the 1975 index are still on sale, price £3.00. **Binders** for the journal are also available at £8.00 for four (a year of *Nature* fits into four binders).

Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

matters arising

The Late Weichselian geomagnetic event

THOMPSON and Berglund¹ describe palaeomagnetic results from Björkeröds Mosse which, they claim, invalidate all previous evidence for a Late Weichselian geomagnetic event. In this note I discuss these results and answer their criticisms in regard to evidence which I have presented².

Thompson and Berglund stress the difficulty of interpreting palaeomagnetic records from sedimentologically complex cores and yet the 'carefully selected site' at Björkeröds Mosse contains eight sedimentary units from three climatic zones. The high noise content of the magnetisation, evident in Fig. 1 of ref. 1, thus supports their contention that variable sediments are poor recorders of the ambient field and this is confirmed by the absence of any secular variation periodicity comparable with cycles in archaeomagnetic data³. Their scattered directions have probably arisen from the spasmodic growth of post-depositional magnetisation, while the general decrease in inclination with depth through layers 8 to 2 is consistent with increasing compaction in these organic sediments^{4,5}. These factors question the reliability of the Björkeröds Mosse data and thus the confidence with which the authors reject all previous results.

In contrast, I have described evidence for a Late Weichselian excursion from a single lithology of exceptionally uniform clay varves from Stårnö, Sweden². Studies of similar varves^{5,6} show that such clays were magnetised depositionally and if sedimentation occurred on a horizontal surface in the absence of strong water currents then the remanence is an accurate record of the ambient field. This is shown, for example at Stårnö, by the virtual absence of noise in varves which satisfy these criteria. The Revised Swedish Time Scale also provides a precise chronology within which to assemble the history of an excursion. At Stårnö the varve data were characterised by a reversal of declination and a shallowing, but not a reversal, of inclination while elsewhere in Sweden southerly declinations with

positive inclinations are a feature of younger varved clays (~8,000–7,600 BC) (ref. 5). As the Björkeröds Mosse core was unoriented, declination values are arbitrary and cannot be used to contradict these observations. Furthermore, according to Berglund⁷ it is impossible to correlate the varved clays in layer 1 with the Swedish Time Scale thus raising doubts concerning any direct age comparison between the Björkeröds Mosse data and results from dated varves.

Thompson and Berglund are correct in emphasising the need for caution when interpreting palaeomagnetic information from sediments, but their suggestion of using the repeatability of between-core directions as a major criterion for confirming the direction of the palaeofield could be misleading. Water movements in a basin are capable of producing large deflections⁸ which can be coherent at separate localities and a similar effect could arise through changing bedding errors⁹ as a basin infills. Thus observation of between-core coherence arising from these factors may mistakenly lead to a 'within-site reinforcement syndrome'. Thompson and Berglund's three-item criteria must be qualified according to individual circumstances and only a detailed consideration of all factors at each locality can decide the reliability of palaeofield directions. The Stårnö data survive as important evidence for a Late Weichselian excursion in Sweden which will achieve creditability as a world-wide phenomenon if palaeomagnetic results from sediments reveal global similarities, yet this is the objective which the authors seek to denounce.

⁷ Berglund, B. *Geol. Förel. Stockh. Förh.* 93, 11–45 (1971).

THOMPSON AND BERGLUND REPLY—Noël¹ assumes that precise palaeomagnetic data are an accurate record of the ancient geomagnetic field. We distinguish between precision and accuracy, and stress the importance of within-site repeatability as one requirement for the recognition of accurate palaeomagnetic recording of geomagnetic excursions.

Noël questions the reliability of our Björkeröds Mosse data² because of his qualitative assessment of the high variability of the sediments and scatter of palaeomagnetic directions. Inspection of the palaeochemical diagrams (Fig. 1 of ref. 3), rather than simply the column of layer numbers, shows that between ~13,000 and 11,000 BP the rate of sedimentation varied from only 50 to 100 mm per 100 yr, the sediment was never coarser than clay grade and that certain of the 'sedimentary units' alluded to by Noël are in fact transition zones. The mean direction of the oriented, cleaned, normally magnetised subsamples spanning the period ~13,000–11,000 BP is dec.=2°, inc.=66°, giving unit weight to each core, with an average 95% cone of confidence of radius of only 3.5° for each core section. We cannot agree with Noël's summary that these data are from sedimentologically complex cores with high noise content.

Noël stresses that "The Revised Swedish Time Scale also provides a precise chronology" for varved clays. Most Swedish Quaternary geologists are now convinced that there is no revised absolute time scale—based on varves—available for South Sweden. There seems to be a discrepancy of 600–800 yr between the varve years and the radiocarbon years south of the Central Swedish Moraines (B.B., in preparation). This is partly due to complications in the varve chronology, partly due to ¹⁴C variations in the atmosphere. Noël consequently uses a floating chronology which is less accurate than the biostratigraphic zones and transferred chronozones of the Björkeröds Mosse sections.

Noël misrepresents our conclusions. Correctly stated they are, "The Swedish late Weichselian reversal has become an example of Watkins's reinforcement syndrome" and "Furthermore, reversals or excursions of the geomagnetic field from other parts of the

world around this time should not be dated or correlated with the earlier Swedish results".

Finally, Noël incorrectly discusses our three minimum requirements as though they were absolute criteria. We reiterate that our criteria are to be regarded as minimum practical criteria for recognising geomagnetic excursions in recent sediments and that they represent only the first of several hurdles which a geomagnetic excursion must pass before gaining recognition as a global phenomenon.

Fairbridge⁴ has recently suggested the Late Weichselian geomagnetic 'reversal' is correlated with a short sharp cold fluctuation in climate. He discusses a mechanism by which climate could be controlled by geomagnetic changes. We would explain such a correlation by an opposite mechanism, namely that sudden climatic changes produce variable sediments which increase the probability of spurious palaeomagnetic data and hence apparent geomagnetic changes.

Liquid nitrogen enhancement of partially annealed fission tracks in glass

PILIONE and Gold¹ described a means of revealing partially annealed fission tracks in glass by immersing the glass (NBS SRM 962)² into liquid nitrogen. According to their discussion it was possible to increase the total number of etchable tracks by increasing the immersion time of the glass in liquid nitrogen. Using this information we attempted to duplicate this work using the same NBS SRM 962 glass.

In a preliminary experiment, we immersed a piece of SRM 962 glass wafer into liquid nitrogen for approximately 8 h. Before the immersion the

glass had been heated to 230 °C for 1 h such that 57% of the tracks were annealed and then the glass was polished. This piece of glass and an unannealed piece, which had previously been broken from the same SRM 962 wafer, was etched in 16% HF at 23 °C for 75 s. Then the fission tracks in both pieces were counted and the track densities compared. The track counting statistics, however, were such that a definitive conclusion could not be drawn.

The experiment was repeated using several pieces of the SRM 962 glass and different continuous liquid nitrogen immersion times. At the end of each given immersion time, pieces of the glass were removed, allowed to reach room temperature, polished, and etched in HF as before. The results of this experiment are summarised in Table 1. We found no significant change with respect to the increased number of etchable tracks in the glass after its immersion in liquid nitrogen.

From our results we conclude that liquid nitrogen has no effect on the annealed tracks in glass. Subsequent discussions with Pilione and Gold have indicated that this effect was only observed when the glass had been polished before exposure to nitrogen. Therefore our conclusion is that the enhancement of partially annealed tracks is perhaps a surface phenomenon and has no effect on the interior matrix of the glass.

² Carpenter, B. S. & Reimer, G. M. *NBS Spec. Publ.* 260, 49 (1974).

PILIONE AND GOLD REPLY—It is apparent from discussions between Pilione and Carpenter that different criteria are used for the identification of fission tracks in glass. But any 'track identification' difference should not affect the results if the density of 'artefacts' remained constant with immersion in liquid nitrogen, because the values reported were normalised in ratio form. We are investigating the effects of

chemical etchants on fission tracks and 'artefacts' in glass, in order to resolve this dilemma. We intend to report in the near future on recent experiments indicating the enhancement effect we noted earlier¹ is probably a surface rather than a volume phenomenon².

Lack of correlation between tight junction morphology and permeability properties in developing choroid plexus

MOLLGARD *et al.*¹ report on morphological study of the sheep choroid plexus during foetal development. Excellent freeze-fracture replicas clearly show no difference in the ultrastructural features of the tight junctions in the choroid epithelium between 40- and 125-d foetuses. The authors reasonably agree that changes in tight junction strand number cannot account for alterations in permeability properties during development, since changes in strand number do not occur.

The reader unfamiliar with the blood-brain-cerebrospinal fluid system is likely to be left with the impression that these results disprove the existence of a correlation between tight junction morphology and permeability in the choroid epithelium itself and therefore in epithelia in general. This is not so. All the permeability studies²⁻⁴ referred to were made in intact animals or foetuses, in which transport of a solute between blood and cerebrospinal fluid can occur indirectly through the walls of the cerebral vessels and the interstitial fluid of brain as well as directly across the choroid epithelium. The observed developmental alterations in permeability with respect to cerebrospinal fluid are probably partly, and perhaps wholly, due to maturation of the cerebral vessels, that is, of the blood-brain barrier^{2,3}. Unless the authors or others can as clearly show for the cerebral endothelial cells of the sheep what has been so well demonstrated for the choroid epithelium, namely that there is no morphological change in the tight junctions of the blood-brain barrier from 40 d gesta-

Table 1 Effect of liquid nitrogen immersion on partially annealed fission tracks in glass

Glass condition		Track density* (tracks mm ⁻²)	Track retention
Not annealed		402.3	100%
Annealed, 230 °C for 1 h	No N ₂ treatment	231.4	57.5%
	1 d in N ₂	231.0	57.4%
	7 d in N ₂	228.2	56.7%
	30 d in N ₂	223.7	55.6%

*Counting statistics (1σ) is ±3%.

tional age to full development, no unequivocal conclusions can be made concerning structure and function in the tight junctions of the choroid plexus from the recorded observations.

⁴ Dziegielewska, K. M. et al. *J. Physiol., Lond.* 258, 86P-87P (1976).

MØLLGÅRD *et al.* REPLY—We thank Dr Bradbury for raising an important aspect of the interpretation of our work which was insufficiently dealt with in our letter because of lack of space. In parallel with our studies of the choroid plexus and cerebrospinal fluid (CSF) we have also studied the ultrastructure of cerebral vessels and penetration of the same markers (non-electrolyte and plasma proteins) into developing brain. We have previously published results of ultrastructural studies of vessels in the immature brain¹. These results, although preliminary, suggested that interendothelial cell tight junctions develop very early in gestation. This has recently been confirmed (unpublished observations) in sheep brain as early as 30 d gestation. The strand number seems to be greater than in the choroid plexus at all ages so far examined. It is technically more difficult to obtain freeze-fracture replicas of cerebral endothelial tight junctions, so it is doubtful if it will be possible to provide evidence for endothelia on the scale already obtained for the epithelial cells of the choroid plexus. However, all endothelial cell junctions so far examined, either by freeze-fracture or by thin section, have had the appearance of well formed tight junctions.

Our permeability data (ref. 2 and unpublished) in 60-d sheep fetuses show that there is more restriction on penetration of protein from blood into brain than into CSF. This implies the presence of junctions which are functionally tight to protein. The data on foetal sheep electrolytes in CSF and plasma³, mentioned by Dr Bradbury, showed that CSF-plasma gradients were present for chloride and magnesium by 60 d gestation. This probably indicates the presence of both the appropriate ion pumps and a permeability barrier adequate to prevent loss of the gradients. Our non-electrolyte

data (ref. 4 and unpublished) suggest that inulin and sucrose penetrate into brain and CSF to a similar degree if the brain extracellular space is assumed to be equivalent to the chloride space. It may be, however, that these materials reach the brain in early development predominantly through the choroid plexus since this is disproportionately large in the immature fetus and the brain is poorly vascularised.

Collagen microfibrils and cell attachment proteins

PEARLSTEIN¹, following Klebe² in the search for a cell attachment protein (CAP) (ref. 3) between mesenchymal cells and collagen, seems to disregard the lesson learnt from Jamieson's similar work on platelets⁴. They omitted to examine the microfibrillar structure of their reconstituted collagen substrata¹⁻⁴. Pearlstein¹ treats his collagen with 8 M urea to minimise 'non-specific' adhesion (see below). But he fails to note that urea inhibits fibrillogenesis⁵, or that collagen-binding both by platelets⁴ and fibroblasts⁶ depends crucially on microfibril aggregation, which also has a key role in the adhesion of BHK cells to a microfibril-forming polysaccharide substratum^{7,8}.

Moreover, the divalent ion requirements of CAP^{1,2} seem to conflict with those of other experiments^{9,10} which do not require CAP for adhesion to various forms of collagen. Rabinovitch and DeStefano showed that Mg or Mn by themselves promote adhesion of carcinoma cells to gelatin⁹, and I have confirmed this for BHK cells on adsorbed films of soluble collagen¹⁰.

Therefore, the fact that aggregation and divalent cations, respectively, can promote adhesion independently of

CAP calls for re-assessment of the "background" of "non-specific" adhesion (that is, in the absence of CAP) subtracted by Pearlstein¹ and Klebe^{2,3}. I suggest that their background adhesion, far from being an inconsiderable artefact, may actually represent a physiologically significant attachment of the mesenchymal cells to aggregated, microfibrillar parts of the reconstituted collagen substrata, under the influence of divalent cation alone; while their CAP-specific adhesion may be to a single-stranded (for example, urea-treated) form of collagen, not found in intact connective tissue. So far, unfortunately, CAP does not seem to have been tested on a physiologically intact form of collagen, such as omentum.

Hence the experiments on mesenchymal cells¹⁻³ should be repeated as those on platelets⁴ have been, that is, with confirmed microfibrils^{5,6}. Moreover, since there is evidence that various mesenchymal cells^{7,8,10-12} explore micro-architectural and mechanical aspects of their substrata, critical work with mesenchymal cells on collagen should also describe the size, spatial distribution and rigidity of microfibrillar particles.

Stereospecificity and clinical potency of neuroleptics

ENNA *et al.*¹ have drawn attention to the potential, and some of the difficulties, of studies of the stereospecificity of neuroleptic drugs in elucidating the anti-schizophrenic action of these compounds. Although they have provided new data of considerable value we feel that they have obscured one issue. There is an increasing body of evidence on the stereospecificity of these drugs in *in vitro* assay systems and some evidence on their effects on animal behaviours, but as far as we are aware there are no systematic studies

of the stereospecificity of the anti-psychotic effect in man. Illnesses comparable with schizophrenia have not been identified in animals although some drug-induced models are available.

Enna *et al.* state that " α -flupenthixol and *cis*-thiothixene are much more potent clinically and in animals than their geometrical isomers β -flupenthixol and *trans*-thiothixene respectively. Similarly (+)-butaclamol is much more potent than its optical isomer (–)-butaclamol". These statements are supported by references which include data from animal behavioural experiments but no clinical findings. Therefore there seems to be a risk that the argument will be accepted that data obtained from an animal model of psychosis (for example amphetamine-induced abnormal behaviours) can provide definitive information concerning the nature of schizophrenia or its response to drugs. We suggest that such information can only be obtained from studies on patients with the disease, although this is difficult and time consuming.

If such studies can be designed to include not only a comparison of one isomer with another but of both with a placebo-treated group they can, however, in spite of the difficulties emphasised by Enna *et al.*, yield information beyond that relating to the *in vitro* receptor systems recently studied. If, for example, it can be shown that α -flupenthixol is clinically more active than the β -isomer and the latter is more active than placebo we may conclude on the basis of the data of Enna *et al.* not only that blockade of the dopamine, and possibly 5-HT, receptor may be relevant to the mechanism of action but that another action is also involved. If, on the other hand, the α -isomer is potent and the β -isomer is no more active than placebo, it seems safe to conclude that actions on those receptors on which the two isomers have been shown to be equally active (for example cholinergic, adrenergic and opiate receptors) are not relevant to the therapeutic effect.

ENNA *et al.* REPLY—Crow *et al.*¹ rightly pointed out the importance of clinical studies in establishing for certain whether drugs, such as isomers of

Table 1 Neuroleptic stereoselectivity at α -noradrenergic receptor binding sites in rat brain

	Affinity for α -receptors	
	K_1 (nM)	Relative stereoselectivity
(+)-Butaclamol	35	70-fold
(–)-Butaclamol	2,500	
<i>cis</i> -Thiothixene	6.6	
<i>trans</i> -Thiothixene	150	23-fold
α -Flupenthixol	10	
β -Flupenthixol	36	3.6-fold

α -Receptors in membranes from whole rat brain were labelled by binding of the potent α -antagonist ³H-WB-4101 (2-([2', 6'-dimethoxy] phenoxyethylamino) methyl benzodioxan) subtracting as blank values binding in the presence of 100 μ M (–)-noradrenaline. Inhibition constants (K_1) were determined by measuring the effects of 3–4 concentrations of each drug in triplicate.

neuroleptics, possess anti-schizophrenic activity. It is commonly assumed that neuroleptics act therapeutically in schizophrenic patients by blocking dopamine receptors so that the isomer which fails to act on dopamine receptors would be anticipated to lack clinical effectiveness. This is only a presumption, which must be directly examined in clinical studies. If supposedly inactive isomers have therapeutic effect, one might assume that they exert part of their action through a system which does not display stereospecificity.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

The focus of our paper² was that some neuroleptics are stereospecific at 5-HT as well as dopamine receptors so that a stereospecific pharmacological action does not necessarily involve only dopamine synapses. Recently we have succeeded in identifying α -noradrenergic receptor binding in brain membranes using an agonist ³H-clonidine or antagonist ³H-WB-4101 (refs 3,4). Several neuroleptics have very high affinities for the α -noradrenergic receptor, often similar to their affinities for dopamine receptors⁵. But, the relative potencies of neuroleptics differ in competing for α receptors and dopamine receptors. Affinity for α receptors parallels closely pharmacological tests of α -noradrenergic blockade and tends to correlate with the ability of neuroleptics to elicit

sedation and orthostatic hypotension⁵. We have now found that neuroleptics display marked stereoselectivity at α -adrenergic receptor sites. The extent of stereoselectivity for the butaclamol isomers is as great at α -noradrenergic receptors as at dopamine receptors (Table 1). The potency of *cis*-thiothixene at α -noradrenergic receptors is similar to its potency at dopamine receptors, though the 23-fold stereoselectivity is somewhat less than that at dopamine receptors. The extent of stereoselectivity of flupenthixol isomers at α receptors is substantially less than at dopamine receptors. As some clinical improvement in psychiatric patients, including schizophrenics, could be associated with 'tranquilizing' effects secondary to α receptor blockade, these receptors and their stereoselective interactions with neuroleptics represent yet another neurotransmitter system which should be taken into account in explaining neuroleptic pharmacology.

reviews

History of African crops

A. H. Bunting

Origins of African Plant Domestication. Edited by J. R. Harlan, J. M. de Wet and A. B. L. Stemler. Pp. xiii+498. (Mouton: The Hague and Paris; Aldine: Chicago, 1976.) Dfl.84.50; \$32.50.

THIS book contains the papers of the 58th Wenner-Gren Symposium on the origin of African plant domesticates, held at Burg Wartenstein in August, 1972. It opens with a series of three general papers, on the origins of domestication and of agriculture in Africa (Harlan, de Wet, Stemler), on causes (Pfeiffer) and on the problems of philosophy, technique and evidence (Higgs). Between them, they spell out the central question—at what periods, where, and why did African people begin deliberately to plant, tend and harvest some of the indigenous food and other useful plants of Africa; and how far, in doing these things, were they affected by influences from Asia? Over these topics controversy has smouldered for many years, alongside the more general endeavour to describe, more satisfactorily, the nature of the Neolithic transition and the emergence and spread of agriculture.

The climatic and ecological scene is set by van Zinderen Bakker. During the last glacial period, up to about 12,000 yr ago, Africa was dry, so that the Sahara spread as far south as 13°N (not S, as an oversight suggests). In a subsequent more or less warm and wet period, cattle, crocodiles and men could inhabit much of what is now desert, and the internal delta of the White Nile reached almost as far north as the modern junction of the Niles at Khartoum. This gave way about 4,500 yr ago to a cooler and drier period which may have driven Saharan man from an Eden of hunting, gathering and fishing into the drudgery of agriculture.

Seven archaeological and cultural/historical papers follow. Three are general (Clark, Shaw, P. E. L. Smith) and four more specialised (Munson, Flight, David, Wendorf and Schild). The evidence comes from a regrettably small number of sites, and there is not yet enough of it to tell a continuous or coherent story. Wheat and barley

from Asia were grown in Egypt more than 7,000 yr ago. It is easy to be convinced that indigenous *Pennisetum*, after being gathered for several thousand years, had given mankind a new crop, bulrush millet, by about 2,500 yr ago. Sorghum and cowpeas appear in West, East and Southern Africa in archaeological contexts, none of which is more than 1,500 yr old. From the Ethiopian plateau there is only one early record, of barley and chickpea, at about 2,500 yr ago.

The last seven papers are on botanical and agricultural topics. Purseglove presents a useful compendium on the crops domesticated in Africa, the history of exchanges between Africa and Asia, and the entry of American species. An essay by Harris on the origins of agriculture in West Africa is based too firmly for me on geographical and ecological 'first principles', but many will find in it, as its author hopes, useful hypotheses to be tested against observations, new and old. Scudder's brave reconstruction of prehistoric land-use in Zambia is illuminated by studies of modern agriculture in the same region. Then the botanists have the last words—on yams (Coursey) and African cereals: sorghum (two papers by de Wet, Harlan, Price and Stemler) and other species (by the late Professor R. Portères, a valuable English summary of over thirty years of devoted and scholarly labour). The two sorghum papers base a geographical history of the cultivated sorghums, starting with initial domestication in the eastern part of the sub-Saharan region, on a range of modern biosystematic and agricultural criteria, but in the absence of early archaeological records the timescale has to depend on the records of sorghum in India 3,000 yr ago.

This book is valuable because it assembles much of what is known, what is said to be known, and what is thought at the present time about the history of African crops. It is strongly suggested that the chief African cereals, and the domesticated yams, emerged without benefit of influences from outside Africa. But the timescales are tantalising: most if not all of the known history happened after agri-

culture had been established in the Nile Valley, and long after it was the basis of a way of life only 400 km away at Jericho and of course further north and east. It is difficult to imagine that the news did not get around. Man, including African man, is far too mobile for that. One wonders whether African oral tradition, difficult though it may be to date, has not a contribution to make here.

It must be important to learn more about human movement in antiquity: the apparently ancient navigation of the Indian Ocean from China to Ceylon, the Gulf, Suez and East Africa, the links across the Red Sea between the similar agricultures of the highlands of Yemen and of Ethiopia, the east-west traffic through what are now the Sahelian and savanna zones from the Blue Nile region (where every *jebel* seems to have been a workshop in days gone by) to the Atlantic; the north-south traffic across what is now the desert from the Mediterranean and the Nile, along the routes—like the *Darb al Arba'in*, the road of forty days—to Kordofan, Darfur, the Tibesti and West Africa (which some suggest brought the builders of stone circles to Senegal and the Gambia, although we know not when).

Then I am tantalised by querns and mortars, the two distinct means by which African people grind grain. The quern, an ancient device in Asia, seems to have spread in Africa before agriculture; the mortar seems to be African. Are the crops and the means for preparing them historically related, and if so, how?

Finally a question about vegetation. Chevalier divided the different sorts of vegetation he saw in West Africa into the forest, savannah and other zones. These correspond broadly with current climates, and many people seem to regard them as 'natural' biogeographical divisions. Yet without exception they are artefacts of agricultural man. What did West Africa look like in the wetter and warmer period 6,000 yr ago, when farming was at most in its infancy? □

A. H. Bunting is Professor of Agricultural Development Overseas at the University of Reading, UK.

Distinguished Arctic explorer

Sir John Richardson: Arctic Explorer, Natural Historian, Naval Surgeon. By R. E. Johnson. Pp. xii+209+33 plates. (Taylor and Francis: London, 1976.) £15.

It is remarkable that this should be the first attempt at a full-length biography of Sir John Richardson since the account by his nephew, John McIlraith, in 1868.

It comes as no surprise to learn that the man who distinguished himself in Arctic exploration, and natural history and introduced reforms in medical practice, was a precocious youth. Apprenticed to a surgeon at the age of thirteen, Richardson began his medical studies at the University of Edinburgh the following year. A little before his twentieth birthday he joined the Royal Navy as an assistant surgeon.

The direction of his life was decided when he was made surgeon and naturalist on an overland expedition to the Canadian Arctic Ocean under Lieutenant John Franklin in 1818. During the next three years this expedition covered 5,500 miles in appalling conditions, losing eleven men, one of whom Richardson was forced to shoot in self-defence. Richardson joined Franklin again as surgeon and naturalist on his second Arctic expedition in 1825, and when Franklin failed to return from his third expedition in 1845, Richardson at the age of sixty-one set out for the Arctic once more in a vain attempt to find his friend.

Sir John Richardson

Mott Collection, Cambridge

Richardson's scientific career began with his zoological and botanical appendices to Franklin's and Parry's accounts of their Arctic expeditions. Sir W. J. Hooker's *Flora Boreali-Americana* (1840) was based principally on the plant collections of Richardson and his very able assistant, Thomas Drummond. His scientific reputation became firmly established through his contributions to the four-volume *Fauna Boreali-Americana* (1829-1837), a pioneer work in Arctic biology.

During his time as physician at the Royal Naval Hospital, Gosport, he created a museum of comparative anatomy and taxonomy which was consulted by scientists as eminent as

Darwin, Lyell, Hooker and Gray. Richardson was a prodigious worker, as the complete bibliography of his books and periodical articles in this book testifies.

Very little seems to have escaped the author's diligent searching for every scrap of information about Richardson. Even the translated text of Richardson's thesis for his doctorate in medicine, *De Febre Flava* (1816), has been included. Research workers in this field will find his list of the main collections of Richardson's letters useful. One of the appendices lists all the known portraits of Richardson followed by the species of animals named by or after him, but through some oversight the plants have been omitted.

In a work that is so full of facts some errors are inevitable: Richardson was elected a Fellow of the Royal Society in 1825, not 1835 (p65); J. E. Gray retired as Keeper of the Department of Zoology at the British Museum in 1874, not 1872 (p114); Sir W. J. Hooker was appointed Director of Kew Gardens in 1841, not 1847 (p114).

Dr R. E. Johnson has methodically assembled all the data necessary for a definitive life of Sir John Richardson. But Richardson does not come alive through his pen, and there is no real assessment of a naturalist who was also one of the outstanding ichthyologists of the nineteenth century.

R. Desmond is Deputy Keeper, India Office Library and Records, and President of the Society for the Bibliography of Natural History.

Process of language understanding

Computational Semantics: An Introduction to Artificial Intelligence and Natural Language Comprehension. Edited by E. Charniak and Y. Wilks. Pp. vii+294. (North-Holland: Amsterdam, New York and Oxford, 1976.)

"COMPUTATIONAL SEMANTICS", say Charniak and Wilks in the preface to their book, "is not so much a new subject as a new way of looking at old questions—those concerning meaning, language and understanding. It is based on the assumption that a good way to explicate such difficult notions is to work toward the programming of an automaton, or digital computer, so that it could be said to understand language." This assumption characterises much recent research in Artificial Intelligence (AI), and it is the AI viewpoint which is strongly put forward by this book.

To demonstrate the significance of this viewpoint, Charniak, Wilks and the other contributors to this volume have placed computational semantics within the context of related language disciplines, providing a broad overview of linguistics, the psychology of language and memory, the philosophy of language, AI approaches to language comprehension, and fundamentals of computer programming. In bringing together all of these cognitive science topics in a tutorial format, the editors have taken an important step towards interdisciplinary consciousness raising. Such an ambitious step is not without flaws, of course—the most serious being the use of heavy attacks on straw men within generative semantics and psychology in order to glorify AI approaches to language comprehension. The drawing of these 'battle lines' detracts from an otherwise noble cause.

The book stands strongly on its positive treatment of tother topics—for instance, it provides an excellent survey of AI language comprehension programs, particularly in the second of Charniak's

two chapters on inferencing and the second of Wilks' two chapters on parsing. Both of these chapters provide clear accounts of recent AI research on language understanding, and suggest some new dimensions along which various AI programs may be compared.

Students interested in theories of language, meaning, and understanding would be well advised to read this book, and to develop a familiarity with all of the areas it covers. Psychologists, linguists and philosophers will no doubt find fault with the sections dealing with their own specialities. If they keep an eye out for straw men, however, they will find that the other sections of the book provide a fine background to some of the most exciting contemporary research into the processes of language understanding.

Marc Eisenstadt, formerly a Research Fellow at the Department of Artificial Intelligence, University of Edinburgh, is now Lecturer in Psychology at The Open University, Milton Keynes, UK.

Major histocompatibility complex

Histocompatibility. By George D. Snell, Jean Dausset and Stanley Nathenson. Pp. xiv+401. (Academic: New York, San Francisco and London, 1976.) \$29.50; £18.

THIS is an excellent book for seasoned professionals and advanced students with a substantial background in mammalian genetics and immunology. Emphasis is on the much studied, major histocompatibility complex (MHC) of mice (*H-2*) and men (*HLA*). It is difficult to find fault with this masterfully written treatise. The coverage is thorough and well-documented. The subject index is admirably detailed. The list of abbreviations given at the outset is helpful in coping with inevitable acronyms. Because so much of the current literature deals with the findings of the past few years, it is also refreshing to encounter each theme in historical perspective. One only wishes the scope extended to non-mammalian vertebrates and invertebrates, but this is newer territory awaiting exploration in depth. This superbly comprehensive volume will be the definitive reference for histocompatibility characteristics of mice and men for years to come. If progress continues at the present rate, however, an updated edition will surely be desired about 1980. The principles so nicely explained in this book should of course remain valid, but the details will surely become more complex.

The first eight chapters take the reader progressively from essential principles of transplantation immunogenetics through allogeneic polymorphism, *H-2* complex loci, and immune response (*Ir*) genes in mice. In chapters 9, 10 and 12, the serology, genetics, and disease associations of the *HLA* complex in man are described in a cogent manner. Chapter 11 deals comparatively with the biochemistry of *H-2* and *HLA* alloantigens. The predominant role played by the MHC in cell interactions, especially lymphocyte interactions such as mixed lymphocyte reactions, cell-mediated lysis, T-B lymphocyte collaboration, and hybrid resistance in mice is admirably presented, especially in chapter 8.

At any given time, every field has a prevailing dogma and histocompatibility or transplantation immunogenetics is no exception. Although emphasis is on the MHC as the only gene complex imposing a "very strong barrier to transplants", the roles of other *H-* or *Ir* genes are trenchantly considered in chapters 3, 7, and 13, the final chapter. Even recipients of *HLA*-identical organ transplants will usually reject such allografts promptly in the absence of drug immunosup-

pression; immunodeficient recipients of allogeneic bone marrow regularly succumb to fatal graft-versus-host disease despite identity for all four *HLA* loci. Other *H* systems then may often have 'major' impact. Moreover, as the authors aver in several chapters, slight preimmunisation with donor-type alloantigens may convert a weak non-MHC barrier into a strong one. Uniqueness of the MHC, if indeed each species has only one such *main system* (book italics), apparently resides in the contiguity of the constituent loci and their interaction. Many of the constituent *H-2* loci taken singly in tests between recombinant congenic lines have effects similar to moderate non-*H-2* loci. In light of other recent evidence, much of the mammalian genome may be organised into large functional units with relevant developmental and regulatory information associated with component structural genes.

Snell, Dausset and Nathenson deal perceptively with discordant findings. For example, divergent data concerning the genetic 'laws' of transplantation, sources of specific immune blocking, and the chemistry of MHC antigens are evaluated in a commendably evenhanded manner. Moreover, they suggest further experiments to resolve ambiguities. An understanding of sequential *HLA* gene-antigen relationships in man has now become difficult for non-specialists. An illustrative diagram proceeding from the chromo-

some No. 6 loci→ alleles and antigens→ haplotypes→ phenotype would have been useful in chapter 9 to epitomise the immunogenetics of the *HLA* system.

Chapter 7 deals concisely with immune response genes and probable mechanisms of *Ir* gene action in mice. This theme is pursued again in man in an incisive chapter 12 on histocompatibility genes and disease—especially associations between *HLA* and disease susceptibilities. The authors favour the hypothesis that *Ir* and metabolic genes closely linked to the *HLA* genes are actually responsible for susceptibility or resistance. Although acknowledging the undoubted relevance of the *HLA* complex to medical genetics, the reader should retain reservations toward the 'MHC controls everything' viewpoint by remembering that many known *Ir* genes are not linked to the MHC; that only a few human diseases (all non-neoplastic) reveal a strong correlation with particular *HLA* specificities; and that animals below the phylogenetic level of advanced amphibians or bony fishes cope quite well immunologically without having evolved a mammalian-type MHC. Altogether, this volume is an outstanding contribution to the field of transplantation genetics and immunobiology.

W. H. Hildemann

W. H. Hildemann is Professor of Immunogenetics and Dental Research Institute Director at the University of California, Los Angeles, California.

Illustrations taken from *Horses of the Camargue*. Photographs and text by Hans Silvester. Preface by Konrad Lorenz. Pp. 23+70 pages coloured photographs. (Phaidon: Oxford, 1976.) £12.50.

Marine pollution handbook

Marine Pollution. Edited by R. Johnston. Pp. 729. (Academic: London and New York, 1977.) £23.40; \$51.

MARINE pollution texts are being published with almost monotonous regularity, and the subject is at best duplicated, but more often fragmentary and of poor perspective. The field is a complex one and calls for a multi-disciplinary approach, and it is not without significance therefore that Dr Johnston has chosen to produce a book by persuading colleagues to write chapters on various specialised aspects.

There are eight contributors to a volume of over 700 pages, with material organised into four principal sections. The first, by the editor, provides a broad brush background to the marine pollution scene, including aspects of fisheries biology and a brief review of the major categories of pollutants, their principal pathways in the marine environment and their potential effects. The second concerns a number of topics of importance to an understanding of the pollution problem, including material on dispersion in estuaries and coastal waters, on heavy metal contamination in the sea, on sewage pollution, on oil pollution and on the impact of pollution on seabirds. The third section is devoted to a review of the problems of measuring biological response; a very intractable problem in terms of the natural environment and one only showing signs of being amenable to treatment in terms of human health. The fourth and final section deals with the legal aspects of marine pollution regulation.

Marine pollution is a very emotive subject, and quite opposing views as to its significance are genuinely held by scientists of all disciplines engaged in oceanographic science. It would be surprising, therefore, if any reviewer could wholly agree with conclusions of one contributor, let alone eight. Nevertheless the book is remarkable in its attempt, particularly in the editor's first chapter, to provide an unbiased view of the subject; and the chapters by Bryan on metals and Topping on sewage are admirable and balanced treatments of their subjects, although Bryan's might have benefited from a slightly more quantitative treatment of the dynamics of metal uptake and loss in organisms.

Cowell's chapter on oil covers much familiar ground but is well presented and readable, although unfortunately marred at the end by an ambiguous statement according significance to mercury pollution. The persistence

of mercury could not conceivably create a global pollution problem since manmade input would have to be maintained at present rates for periods commensurate with the residence time of mercury in the oceans, say 10^4 yr, before a significant increase in the worldwide concentrations of mercury in the oceans could be achieved. It is therefore misleading to state that persistence can necessarily be equated with global contamination, although it may be in surface waters if the pollutant is distributed by way of the atmosphere, as in the case of DDT.

The chapter by Bourne on seabirds and pollution makes interesting reading, and he rightly points out that vulnerability of birds at the end of marine food chains, and the conspicuous way in which dead animals are seen on the strand lines of beaches, often provide the earliest indication of unacceptable situations arising at sea.

Muscular exercise

Biomechanics and Energetics of Muscular Exercise. By Rodolfo Margaria. Pp. x+146. (Clarendon: Oxford; Oxford University: London, 1976.) £7.

It is a pleasure to read a book by an expert expounding his life's work, an *auto-festschrift* as it were. Professor Margaria treats the reader to a feast cooked by a master chef, beginning with an historical note in which he himself appears as making a crucial contribution to the lactic acid-oxygen debt controversy. He leads us, by way of his own and his colleagues' work, through the intricacies of the sources of energy for muscular contraction, quantifying the contributions made by oxidation, glycolysis and phosphagen cleavage (the lactic acid and alactic oxygen debt). There follows a very short and somewhat cryptic chapter on some of the cardiorespiratory changes in exercise. Here is the only serious attempt within the book to use SI units; the style and content make one suspect another and less thoughtful hand. The third and final section is entitled "The biomechanics of human locomotion", in which there is a very clear description of how mechanical work may be measured and the interesting conclusions that may be drawn. The author holds out hope for the non-athletic that they too will be able to run at world (Earth) record speeds when the Olympics are held on the Moon.

The book reflects the character of the man; every now and then the

These, of course, are not always related to pollution.

The final chapter by Moore on legal aspects is a most useful review of the subject. Particularly welcome is the clear expression of the view that the function of marine pollution control is not to prohibit entirely the introduction of wastes to the sea, and that indeed the ability of the sea to absorb and assimilate waste is one of its most valuable resources: rather that marine pollution is part of the conflict between the need to release some contaminating materials to the sea and the desire to maximise the use of the marine environment as a source of food and for recreation and transport.

Alan Preston

Alan Preston is Deputy-Director of Fisheries Research in the Ministry of Agriculture, Fisheries and Food based at Lowestoft Laboratories, and Chairman of the UK Marine Pollution Monitoring Management Group.

complex and erudite arguments are interspersed with friendly pieces of practical advice, inviting the reader to relax his mental grip just for a moment. Nevertheless, the book is not for the faint-hearted, the skimmers or the dippers; it is closely argued and requires dedicated concentration. The mathematics, of which there is a good deal, is helpful and yet simple to follow; no-one need fear the book on that account. The author pleads for the adoption of his findings in everyday life—this unfortunately is the *cri de coeur* of many human physiologists! He spoils the case a little, however, by presuming his own degree of expertise in others; how many, for example, would describe his test for maximum anaerobic power as simple? In a world in which rapid communication is producing a tendency to dull uniformity it is interesting to note that schools of thought may still differ on the most practical matters—in Milan the stepping stool reigns supreme for almost the same stated reasons that the bicycle ergometer holds sway in Sweden.

To whom then would this book be useful? Most definitely for the serious and advanced student, but it cannot be unreservedly recommended as a standard text. Although one may overlook the occasional slipshod editing of text and figures, the use of the old units (calories and kilogram-metres), with never a joule or a watt, panders to middle age, prolongs our difficulties and introduces unnecessary confusion for those nearer the starting line.

Rainer Goldsmith

Rainer Goldsmith is Professor of Physiology in the University of London, UK.

obituary

D. H. Menzel

PROFESSOR Donald Howard Menzel, past director of Harvard Observatory, who died in Boston, Mass. at the age of 75 years on December 14, 1976, was born on April 11, 1901 in Florence, Colorado, and educated at the Universities of Denver and Princeton where he received his doctorate in 1924. After several junior appointments of short duration he joined, in 1932, the staff of the Harvard University which remained his academic home until his retirement in 1971. Within his lifetime he took an active part in the transformation of the American scientific scene from its grass-roots stage to the "big science" which it has become—for better or worse—today.

When Menzel left Princeton in 1924, he was a young theoretical astrophysicist—of whom there were not many in the United States at that time—bent on applications of atomic physics to astrophysical situations, and his first interests centred on the physical processes in gaseous nebulae. In collaboration with several students of his who have since attained a renown of their own (and among whom L. H. Aller and J. G. Baker should particularly be mentioned) throughout the 1930s Menzel made important contributions to the subject which are still well-remembered today.

Another field to which Menzel then turned his professional attention, and to which he remained faithful for a major part of his life, was the Sun. The excitement which Bernard Lyot created in the late 1930s with his observations at Pic-du-Midi of the solar corona outside total eclipses, and his films of the activity of solar prominences, is still a vivid memory among the survivors of that heroic epoch. Menzel was the first to transplant these techniques across the Atlantic, and his efforts led to the foundation in 1939 of the High-Altitude Observatory in the Colorado Rockies near Climax, Colorado, at an altitude of over eleven thousand feet—first as an offshoot of Harvard, and later as an independent institution, which only recently closed its doors because of increasing pollution of its environment (caused by nearby mining activities).

Unlike Lyot, who was a genius at improvisation and preferred to perform experiments with his own hands (to the extent of carrying the crucial parts of his coronagraph to the top of Pic-du-

Midi on his back!), Menzel was a theoretician of managerial type, who worked through other people's hands. His field executive in the Climax operation was mainly Walter Orr Roberts, another student of Menzel's who retired only recently from the directorship of the National Centre for Atmospheric Research in Boulder, of which the High-Altitude Observatory eventually became a part.

Then war came (in which Menzel served his country in the uniform of a reserve naval officer) and with it changes in academic and scientific life which were fully reflected also in Menzel's subsequent career. Like many others, after 1945 Menzel never returned properly to resume the career of a scholar, and his activities veered increasingly towards those of an administrator and promoter of science. These latter abilities, which were at a premium during the years of post-war inflation, eventually led to Menzel's appointment in 1954 as Director of the (then) Harvard College Observatory—a position in which he succeeded Harlow Shapley and which he held for the next 12 years.

His illustrious predecessor possessed, among his many talents, an uncanny gift (perfected during his apprenticeship with G. E. Hale) to extract money for astronomy from rich Americans, with which to augment his observatory's current income. In postwar years this goal proved doubly desirable, but no longer attainable in the old ways; for fewer Carnegies were left in the world (income tax saw to that) and, instead, most available funds were to be found in the hands of the Federal Government in Washington. As a result,

Shapley's successor had to seek additional support for his institution, no longer by waiting on the rich, but by lobbying in the "corridors of power" in Washington for grants or contracts from different branches of the Government through their many agencies.

This was an ominous turn of events for the further development of American science; for while rich Americans were (sometimes) willing to make gifts for a good cause with no strings attached and very little paperwork, the new dispensers of Government largesse knew exactly what they wanted and saw to it that they got it. As a result, the Harvard Observatory during Menzel's regime got often involved in work in new fields, such as geophysics, in which it had neither tradition nor sufficient expertise. At times, the Observatory seemed to differ only in location, but not in spirit, from the many research laboratories which sprang up during the "roaring sixties" along Route 128 around Boston as offshoots of Harvard or M.I.T. to serve the customer rather than science—at a time when men were heading for the Moon, and when nothing seemed impossible on Earth.

It is remarkable that, in this atmosphere and with so many administrative preoccupations, Menzel found also time to write or edit a considerable number of books (by himself, or in collaboration with others), ranging from collections of mathematical formulae to polemics about UFOs. Some, like his popular book on the Sun, enjoyed a well-earned popularity in their time, but none seems to have left any deeper mark on contemporary science.

Needless to say, a life so busy has its drawbacks for institutions as well as the individuals directing them, and Menzel was no exception. His health suffered a serious setback in 1965 from which he never fully recovered. He retired from directorship in 1966, and although he continued to teach students until 1971, as a scientist Menzel was essentially on the side-lines—occupying his mind with problems of such gravity as lunar nomenclature, and leaving it to his successors to pick up the more important pieces of the game. Death claimed him last December at the age of 75 years, after a prolonged illness; he was survived by his wife (née Florence Kreager), two daughters and six grandchildren.

No error-free society

NOTHING ventured, nothing gained—the calculus of risk and the trade-off between benefit and damage is much in the news at present. This is partly due to the growing public interest in decision-making in the nuclear industry, but some of the credit in Britain must go to the Council for Science and Society (CSS) which has had a study group looking at the question of acceptable risk and which this week convened a public meeting on the subject.

There is something almost irrational in our variable attitudes to risk-taking. The hazards of cigarette smoking are well enough known, are not by any means negligible, often involve others quite involuntarily in a long period of distress and yet are clearly deemed acceptable by a large section of the public. The same might be said of combining drinking with driving. And yet at the other end of the scale those same inveterate risk-takers may show profound shock on hearing of ten people being killed in a coach crash or may express the strongest opposition to the building of a nuclear power station with a claimed minute chance of having a serious accident. We may live in fear of a major accident in which a thousand might die even though, as Reg Farmer pointed out last week (page 93), such an event would barely affect the accidental death rate. It somehow seems that the idea of one or two people being responsible for many deaths strikes a very profound note in the public conscience. Desirable as this is, it inevitably dampens down public concern for how to cut down on the smaller scale accidents.

A frequent rallying cry amongst those concerned with hazards is that as technology grows so does the risk. Even the CSS will say in its working party's report 'popular concern about risks has increased recently, as man-made disasters carry the threat of even worse to come from new or projected technologies'. A more technological world may indeed open up the possibility of human error causing more deaths; the six hundred deaths on Tenerife would have been only one hundred from a similar accident twenty-five years ago. But all in all the fatality rate for air travel has been steadily declining during this same period that the potential for bigger tragedies has been growing, so maybe the intro-

duction of new technology, some of which is safety-oriented, has had a beneficial effect.

Because things have improved in one well-studied industry doesn't, of course, mean the same will happen everywhere, and it is obviously right that we should go on asking more and more searching questions about safety. But modern scientific analysis coupled with intensive computer simulation of hazards can easily give the public a false impression that by better and deeper study the present-day technologist can give more and more assured guarantees that anything newly introduced will be 'safe'. As accidents from the trivial to the severe show, however, human actions, logical in themselves but illogical in a broader context, are at the heart of many disasters. These actions can never be properly simulated—who would have put a candle into the computer program for safety at Browns Ferry?

What we have to do if we really want the benefits of new technology is to be prepared for some mistakes to find their own way out—a principle, incidentally, followed throughout the whole process of scientific advance.

Obviously we don't allow a few stored nuclear weapons to go off by accident in order to learn how they can be safely stored, but in many environments, such as factories, air traffic, coal mining, novel engineering structures and so on, it is only with the help of an occasional accident, however distressing, that some very important and valuable pieces of information ever emerge. In an age in which the public expects scientists and technologists to think of everything ahead of time, this idea of learning from mistakes is often forgotten. But to learn effectively, the after-the-fact enquiry must be very wide ranging, because accidents, even road accidents, frequently result from a string of errors, sometimes apparently of little relevance. Thus one requirement, insufficiently widely discussed, in risk reduction is that the scope of enquiries should not be too severely circumscribed. This is a political matter and decisions are often taken against a background of fears of a 'fishing expedition'; maybe there is some good research to be done on how wide committees of enquiry should spread their nets. □

When is a drought a drought?

Michael H. Glantz and Richard W. Katz, of the Environmental and Societal Impacts Group at the National Center for Atmospheric Research, Boulder, Colorado, draw on the case of the Sahel to comment on the use of the term 'drought' for arid regions

THE word 'drought' has various interpretations: decision-makers, political and otherwise, underestimate its likelihood in and around regions where interannual rainfall variability is relatively high. In such arid and semiarid areas, recurrent droughts are in fact a part of climate and not apart from it, and therefore should not be viewed as unexpected events.

The West African Sahel, one such area, has recently been affected by its third major extended drought this century. Many observers have suggested that the drought, which began in various parts of the region in 1968, ended with a return to normal or near normal rainfall. Some interpreted the relatively good rains in 1974 as indicative of a resumption of 'normal' rainfall. Similar statements have been common in the growing volume of drought literature. However, they can mislead because they imply that a return to normal rainfall, that is, rainfall seen as an 'average', is associated with a return to acceptable if not favourable meteorological, agricultural and social conditions for the region. The validity of such an assumption is questionable.

What is perceived as 'normal' rainfall is an important, yet often overlooked, aspect of what is meant by 'drought' in arid and semiarid regions. People react to their perceptions whether or not those perceptions are based on reality, and the consequences of those reactions are real. It is misleading to view 'normal' as a 'normative quantity' with the implication that a departure is 'abnormal': a 'normal' has no predictive value. The literature concerned with droughts in arid and semiarid regions is replete with references to particularly dry years as being abnormal or anomalous. Yet, because perceptions about what con-

stitutes a drought vary, there is no widely accepted definition of drought. The scores of existing definitions, however, are either meteorological or agricultural. A meteorological drought could arbitrarily be defined as that period when the amount of precipitation is less than some designated percentage of the long-term mean, whereas an agricultural drought could be defined in terms of the timing of the rainfall which is crucial to crop development.

In reality, the subjective distinction between a dry spell and a genuine drought is a difficult one to make. Most American farmers do not call a dry spell a drought until the moisture shortage has seriously affected the established economy of the region. These observations apply equally well to similar situations in arid areas. It has been suggested that there should be at least two components to a definition of drought: a physical one and a social one. A mix of dry spell and meteorological drought occurred at various times and various places in the Sahel between 1968 and 1974, but their impacts were worsened by the pressure of populations, both human and livestock.

A major problem associated with the perception of drought is the constantly changing nature of those perceptions. Recent weather tends to influence perceptions more heavily than earlier weather and wet spells more heavily than dry ones. On this basis it has been suggested that the inhabitants of the Sahel have adopted practices during the abnormally wet years which end in disaster during the dry years. After a period of abnormally high rainfall in the Sahel which ended about 1965, the inhabitants considered a return to average conditions for rainfall to be a 'drought'.

What, then, does a return to average rainfall conditions in arid and semiarid regions mean? Of what importance is it when a return to 'normal' or near normal rainfall is perceived to be a return to drought-like conditions? Take the case of the Sahel, a climatic zone in sub-Saharan Africa which receives 200–600 mm of annual mean rainfall. It is bordered on the north by subdesert (100–200 mm) and to the south by the Sudan (600–900 mm). Rain falls during

August precipitation 1941–75

convective thunderstorms over a four-month period beginning in June. It is this highly variable rainfall on which the region's inhabitants depend for the cultivation of their crops and the maintenance of their herds.

August rainfall data are significant in that August is nearly always the wettest month and it marks the midpoint of the rainy season. We have looked at rainfall statistics for arid zones by taking the August rainfall records for two cities within the Sahel—Gao, Mali (16.3°N, 0.1°W) and Niamey, Niger (13.5°N, 2.1°E)—and have found that Sahelian rainfall shows a relatively high degree of variability. Many analyses, however, have not included a plot of the actual data but have relied on the use of descriptive statistical terms such as the mean or the running mean. Such terms fail to reveal magnitude and variability which are major factors in understanding the nature of rainfall in arid and semiarid lands.

Histograms derived from the data for Gao and Niamey show a 'positively skewed' frequency distribution, small amounts of rainfall occurring more frequently than relatively large amounts. This type of skewness is characteristic of the rainfall distribution not only in the Sahel but, more generally, in arid and semiarid regions. In particular, the degree of skewness is greater the drier the climate.

The mean, which is commonly taken to represent 'normal' rainfall, is extremely sensitive to skewness because it is inflated by the relatively few cases of large values: more than half of the observations fall below the mean. As a result, rainfall observations close to the mean value do not occur often in the Sahel, showing that, at least in some sense, the mean is too large and not at all indicative of how much rain commonly falls.

The median marks the amount of precipitation which is exceeded one half of the time, while the mode represents the amount of precipitation which is most likely to occur. Since neither of these measures is greatly affected by skewness, their interpretations remain clear. In particular, for a positively skewed distribution they are usually smaller in value than the mean.

For the Sahel, therefore, the mean, in reality, is above 'normal', while the median and the mode can still be interpreted, in the sense just discussed, as 'normal'. Hence although most analyses of Sahelian rainfall assume that the mean is an appropriate measure of central tendency, either the median or the mode may, depending on the circumstances, be preferable and no single number can adequately represent the distribution of Sahelian rainfall, given the large deviations from each of the measures of central tendency. 'Normal' rainfall, however, can be better characterised by the interquartile range than by any of the standard measures of central tendency.

Measuring the variability of Sahelian rainfall is further complicated by the possibility of trends or cycles or other evidence of climatic change in the data: there is strong disagreement among researchers over whether significant trends or cycles do exist. Although they might well exist, there may have been an inordinate degree of effort devoted to 'hidden periodicity' research and this has tended to obscure the most important aspect of Sahelian rainfall—its extreme variability. In fact, even if trends or cycles do exist, it is almost universally agreed that they would be of limited predictive value.

Aside from the absolute amounts of rainfall, as measured over varying lengths of time, other factors such as spatial distribution, timing, wind velocity and evapotranspiration could have an important impact on the social value to the inhabitants of the rain that does fall. If rainfall information, which represents only one climatic variable, is not viewed within its total environmental context, it can be extremely misleading. Where long-range development planning is concerned, such an oversight can be disastrous. Such has often been the case in fragile ecosystems like those in

Camera Press

arid and semiarid regions.

Desertification—the creation of desert-like conditions where none had existed before—is the result of either the vagaries of weather and climate or the mismanagement of the land or, as in most cases, some combination of both. Such ecological deterioration in the Sahel has been linked in several ways to the increased sizes of livestock herds. During extremely favourable periods of rainfall, as was the fifteen-year period preceding 1968, the pastoralists moved into the marginal regions in the north with relatively large herds. However, with the onset of a series of dry years beginning at the end of the rainy season in 1967, the pastoral populations found themselves overtaxing very marginal range-lands with the result that the nomads viewed themselves as victims of a natural disaster.

Deterioration and ultimately desertification in the Sahel and in similar ecosystems could be combated if an ecologically realistic carrying capacity for the rangelands was determined. Although there appears to be widespread acceptance that such a determination would be significant, there has been little agreement to date on how to make operational the notion of carrying capacity (defined as the amount of grazing stock that the pasture can support without deterioration of either the pasture or the stock). Should the carrying capacity be geared to the best, the average, or the poorest years? Which combination of statistical measures would be most meaningful for the planning of long-term development of rangelands? On which variables should such an assessment be based—vegetation, rainfall, soil, ground and surface water, or managerial capabilities? Such inconclusiveness within the scientific community, while understandable, creates confusion for the decision-makers, who often decide either to take no action or who decide that all scientific suggestions are of equal weight and, therefore, indiscriminately choose any one of those suggested. Given the downward spiral of land deterioration it becomes essential that an ecologically acceptable carrying capacity be established and enforced.

The mistaken idea that drought in the Sahel is an unexpected event has often been used to excuse the fact that long-range planning has failed to take rainfall variability into account. People blame the climate for agricultural failures in semiarid regions making it a scapegoat for faulty population and agricultural policies. It will therefore be crucial that decision-makers know what statistical and quasi-statistical measures actually mean: no single number can adequately describe the climate regime of an arid or semiarid region. Decision-makers must supplement such terms as the 'mean' with more informative statistical measures to characterise adequately the variability of the climate. An understanding of this high degree of variability will serve to remove one of the major obstacles to resolving the perennial problems of the Sahel and of other arid or semiarid regions. □

Going on the defensive

Constraints on the UK chemical industry are affecting research in its laboratories. **John Manos** describes how

THE chemical industry has suffered some nasty shocks in recent years. The basic economics of oil-based petrochemicals production has been severely shaken by rises in the oil price, while in other sectors the industry has had to face the onslaught of environmentalists and regulators.

Because the industry is more research-based than most, it is not surprising that these pressures should have had their effect in directing work in its laboratories. But they are not the only factors which have contributed to a major shift in research aims. In general, a growing maturity in the private industry's end products together with the above constraints (and the economic pressures of a recession) have meant that research effort is increasingly described as 'defensive', allowing companies to maintain their existing positions in the face of controls and inflation, while consolidating their expertise in established product areas.

Research is increasingly devoted to 'replacement' ventures, in which old processes, extravagant on energy and raw materials, are replaced by new processes economical in both. By applying a total design or total systems concept, the industry is re-training itself to satisfy this new long-range research aim. Also the paucity of totally new products which have provided a satisfactory return over the decade, has meant that less and less effort is devoted to 'blue sky' research and the research function is having to gear itself to satisfy more of private industry's short-term aims. That means fewer new drugs and pesticides and no really new plastics.

This applies to both those polymer products which showed spectacular growth over the past twenty years and to the higher value fine chemicals, drugs and agrochemicals whose development is more readily associated with broadly-based laboratory research aims. In both these areas less than 10% of research effort is now spent on the search for new products, the increasingly competitive nature of the business now requiring that 90% be spent on improvement and widening the range of products and on reducing costs.

The bulk petrochemicals industry, which has allowed the rapid growth of polymer production to take place, has reached a different sort of maturity. The petrochemicals industry believes

that Europe should have an energy policy that preserves for the chemical industry the chemical structures in 5% of total oil production, oil being too valuable to burn. If governments behave foolishly, the industry in Europe is considering which raw materials will replace (and to what extent) the cheap naphtha refinery by-product on which it has grown up. Research here is economic analysis of how best new feedstocks can fit in with established downstream production. While governments and state industries look at (or talk of) long term possibilities for the exploitation of new bulk raw materials, such as associated gas from North Sea oil wells or even coal, private companies are pre-occupied with justifying the operation of their existing facilities.

Biochemical engineering

If there is a pattern characterising research trends that is not symptomatic of the search for energy economy, pollution-free processes, or quickly exploitable product refinements, it is the opening up of entirely new areas of business based on the extension of chemistry into biology, and chemical engineering into biochemical engineering. It is surprising, for example, that each of the UK's big three chemical companies (and one of West Germany's) should have devoted such great research effort in seeking to move into the animal feedstuff industry. Yet this illustrates one of the chief areas of diversification: biochemical engineering.

In commercialising their bioproteins (or single cell protein) processes, BP, ICI and Germany's Hoechst are entering into a commodity business which is less well-known to them. In fact it is uncertainty about future price trends of the natural products which they aim partly to replace—soya bean and fish meal—which the third UK company, Shell, cites as the reason for its withdrawal from the development race. Nevertheless, 20% of ICI's 1977 capital investment sanctioning is devoted to a 50–75,000-ton-per-year plant to produce pig and poultry feed from hydrocarbon (methanol) feedstock. Methanol is also used in another animal feed development of ICI's at Billingham.

The bioproteins development programme has cost ICI £10 million over the past eight years with half spent in the last three. In its 1977 report, ICI

'Pruteen' piglets

describes this as a result of its 1960s initiative in applying process engineering know-how to microbiology. It is part of a bio-sciences research policy which the company has increasingly pursued in cooperation with universities. Other products of this line of research include processes for the continuous production of enzymes for the food industry (particularly isomerase for the production of high fructose corn syrup, for which ICI is now building a US manufacturing plant) and ICI's 'deep shaft' waste water treatment process which uses a mildly pressurised biochemical reaction to accelerate the conventional treatment process.

The forces which have encouraged the majors to venture into such unknown areas are the same as those which make research management in existing areas of business so difficult: the need for speedy exploitation of new developments countered by the increasingly long lead times to get new chemical products on the market. This latter point has been well documented for the agrochemicals industry where resources required to carry new insecticide through its seven- to nine-year path of screening, toxicology, field trials, registration and marketing are such as to restrict innovative development to only a small number of major companies.

Development effort

The development effort has swung over to what are generally less toxic products such as herbicides, or to the development of more efficient methods of applying existing compounds: ultra-fine sprays, slow release and encapsulated insecticides. Also newer synthetic pyrethroids under development are safer than the organophosphorous and carbamate products which are themselves safer than the organochlorines (which include DDT, aldrin and dieldrin).

Plant design and construction has been one area where companies have attempted to shorten development time. Shell Chemical, for example, has invested £19 million in a flexible agrochemicals production facility at Pernis, Rotterdam, which, although initially dedicated to specific products, incorporates in its design a service and equipment flexibility which will allow a switch to production of another product in as little as two months. But Shell still regards agrochemical development as a high-risk area from which resources will be diverted to more profitable business unless the regulatory pressures are eased.

The need to accelerate the worldwide exploitation of new developments is cited as one of the reasons why the overseas research budget of ICI has increased in recent years (from 25–30% of total in 1976). Thus, in the USA, ICI has extended its pharmaceuticals research effort so as to have the advantage of a scientific dialogue across the North Atlantic; and in India it is hoping to set up some central research facilities that will better use indigenous Indian raw materials within the Indian economy.

In general, however, rationalisation means centralisation, as illustrated by Hoechst and Shell's plans for their research facilities in Europe, although ICI still believes in a great deal of autonomy for its separate major business area. The greater part of Hoechst's investment in research facilities in recent years has been in its new multidisciplinary centre being built up in Frankfurt, which the company feels is necessary to cope with the rapidly changing demands of the market and of raw material supplies. Similarly last year Shell completed the transfer of all chemicals and polymers research facilities outside North America (except for agricultural pro-

ducts) to one site in Amsterdam.

As with agrochemicals, polymer research trends have been greatly influenced by the need to consolidate positions of strength and refine the properties of mature products. Hoechst notes that of the twelve plastics which represent 90% of Germany's consumption, not one has been developed within the last ten years. Polypropylene is the fastest growing new bulk plastic which threatens to compete strongly with the ethylene-based polyethylene, PVC and polystyrene (which account for 80% of German consumption) but this good rate of growth has come after twenty years of development! Other unique new materials such as carbon fibre, the wonder material of the sixties, have been overtaken by existing polymer technology which can satisfy rapidly changing customer demands more quickly and cheaply. The day of the accidentally-produced polymer having a market developed for it have passed.

The same accent on the selective development of established products was echoed by Shell last year in opening its polymer research centre in Amsterdam. It was suggested that the company, which had already withdrawn from two polymer areas (general-purpose rubber in the USA and high density polyethylene in the UK), might withdraw from other areas if its position was not strong. Certainly some polymer areas have shown a poor profitability recently. But as a number of products reach maturity over the next few years, Shell hopes that the concentration of product-oriented research capability at Amsterdam will allow a broadening of the range of applicability while process research is directed towards the development of improved, or second-generation processes for the production of the same polymers.

Non-productive research

Perhaps the most rapidly growing research area, however, is that involving non-productive work associated with toxicology and the control and detection of carcinogens. The complaints about over-regulation now heard from the agrochemical sector come more than a decade after the first problems associated with the use of agricultural chemicals caught the public eye. It was in the 1950s that concern over such products as the insecticide DNOC (dinitrocresol), which had caused the deaths of four farm workers, resulted in the setting up of the UK's Pesticide Safety Precaution Scheme. But increasingly stringent screening and animal testing techniques have always played a major part in product development in the agrochemical and the pharmaceutical industry. Exposure

limits and precautions for use of other chemicals not in contact with people or vegetation have generally been retrospective, based on experience of the chemicals in use.

This will not be so in the future. The 'ecology movement' and the need to avoid the difficult problem of dealing with a widely-used and manufactured product which is subsequently found to be dangerous and/or persistent in the environment will mean far tighter control on the introduction of all new chemical products. The US industry is already grappling with the massive requirements of the Toxic Substances Control Act and similar legislation is presently being formulated in Europe.

One of the biggest problems is the control of cancer-causing substances, or those which have given indication that they might be carcinogenic. The furore created by the US Food and Drug Administration's recent restrictions on the use of the sweetener saccharin and plastic soft drink bottles containing acrylonitrile indicates, according to the more pragmatic European view, the disadvantage of adopting a strict legalistic approach to the problem. But whatever the control strategy employed with known carcinogens, the problem remains simply how to screen new products for carcinogenicity to avoid the problem arising. With the several thousand new chemical products introduced every year being required to satisfy this sort of criterion, there is an urgent need for a simpler, quicker and cheaper screening procedure in preference to the conventional lengthy animal studies.

One of several possibly applicable *in vitro* tests is the Ames test, developed in the USA, which uses the mutation of bacteria strains as an indication of possible carcinogenic potential. For US companies such as Dow Chemical, currently spending 15% of its R&D budget on toxicology, such developments are of major importance in the light of new legislative requirements. But in Europe, too, *in vitro* testing is a major research area: ICI's central toxicology research laboratories have further developed the Ames test (in combination with another test involving mammalian cell transformation) to give the most reliable *in vitro* indication of carcinogenicity yet developed.

This exciting project is already justifying a budget of £250,000 a year which will rise to about £750,000 a year by 1978–9. Through such techniques, the company also sees a possible resolution of the problem of establishing no-effect levels for exposure to carcinogens, possibly within five years. □

USA

Space in a corner

A tough fight is in prospect over two important space science projects for which funding is threatened. Colin Norman reports from Washington.

THE budget for the National Aeronautics and Space Administration (NASA) has run into unexpectedly heavy weather in its passage through Congress, and two major scientific projects could be in trouble. They are the Large Space Telescope, an orbiting optical telescope which has long been regarded by space scientists as NASA's top priority space science project, and the Jupiter Orbiter Probe, a proposal to launch twin spacecraft early in 1982 to orbit Jupiter and send probes into the planet's atmosphere.

A key subcommittee in the House of Representatives has already voted to block funds for the Jupiter project, and a sharp attack on the space telescope is expected in the Senate, with Senator William Proxmire leading the charge. Proxmire occupies a pivotal position since he is chairman of the subcommittee which is handling NASA's budget in the Senate; he is also armed with a new analysis suggesting that the total cost of building and operating the space telescope could run as high as \$1,400 million.

Though it is possible that both projects could be rescued by an intense lobbying campaign, already being mounted by NASA and its clients in the scientific community, loss of either of them would be a serious blow to the space science programme.

Both projects have been on the drawing board for some time, and NASA is now seeking Congressional approval to move them into the development stage. It has requested \$36 million for the space telescope and \$20.7 million for the Jupiter Orbiter Probe in fiscal year 1978. Those sums represent the first instalments toward the total development costs of \$435 million for the telescope and \$285 million for the Jupiter project, according to NASA's latest estimates.

Opposition from Senator Proxmire to the space telescope has long been anticipated, but the moves against the Jupiter project seem to have caught NASA officials by surprise. The first sign of trouble came late last month, when a House appropriations subcommittee deleted funds for the project from NASA's budget request. The subcommittee is said to have been unwilling to allow NASA to begin two

major projects in one year, and since subcommittee members had been under heavy pressure from space scientists to approve the telescope, they opted for that project and voted to kill off the Jupiter mission.

The subcommittee's recommendations will be reviewed by a meeting of the full House Appropriations Committee next week, but it is considered unlikely that the funds for the Jupiter project will be put back at that stage. Similarly, it would be unusual for the full House to overturn the committee's recommendation by restoring the funds. NASA is therefore concentrating its lobbying efforts on the Senate in the hope that if the Senate approves the project, House members can be persuaded to follow suit when differences between the House and Senate versions of the NASA budget bill are eventually settled in a House-Senate conference committee. The crucial vote will come in mid-June, when Proxmire's subcommittee is due to vote on NASA's budget bill, and the outcome is difficult to predict for a variety of reasons.

The chief focus of attack in the Senate is likely to be the space telescope, and Proxmire has already fired his opening shot. The Large Space Telescope (LST) has been under serious consideration by NASA since the early 1970s, and it has been consistently and enthusiastically endorsed by astronomers. Due to be launched by the space shuttle in 1983, the LST would have a major advantage over ground-based telescopes: the light it receives would not have to penetrate the semi-opaque curtain of the Earth's atmosphere, which filters out all but a narrow band of colours and blurs distant objects. As a result, the LST would be able to 'see' objects about 10 times smaller than those that can now be picked up

by the most powerful ground-based instruments, and it would be able to search for objects emitting light from the far infrared to the far ultraviolet, a range one thousand times larger than Earth-bound instruments.

Though the telescope has always been popular among scientists, it has not received unqualified support from Congress. A couple of years ago, before NASA had even asked Congressional approval for the LST, the House Committee on Science and Technology directed the agency to seek international participation in the project, to help defray some of the costs. Consequently, NASA has established a European connection. Last October, the Science Planning Council of the European Space Agency (ESA) approved a contribution of some \$80 million to the project, and according to NASA officials, a formal agreement will soon be signed under which ESA will supply a faint object camera, a solar array, a number of scientists for the project team, and assistance in maintaining and overhauling the telescope.

The LST has already been considerably delayed. NASA was originally hoping to begin building the instrument this fiscal year for launch in 1982, but the project collided with President Ford's attempts to hold down government spending. The Office of Management and Budget deleted funds for the LST from NASA's fiscal year 1977 budget before the budget was sent to Congress. According to NASA officials that delay has already hurt the project and a further delay would probably kill it. It would be difficult to keep the design teams together for much longer, they argue, and European support would probably melt away if Congressional approval isn't assured.

Proxmire opened his assault on the LST last week by releasing a report prepared by the General Accounting Office (GAO) which suggested that the

Space shuttle placement of LST

total cost of building the telescope and operating it for its projected 15-year lifetime could amount to \$1,400 million. "The country faces an \$80 billion deficit, and it is time the Congress said 'no'. The space telescope is a good place to start", said Proxmire.

The GAO essentially took NASA's estimate for \$435 million to develop the LST, and added \$96 million for inflation, \$65 million for tracking and data acquisition, \$470 million for general operations costs, \$81 million for civil service personnel, and \$211 million for shuttle launches to put the instrument into orbit and to refurbish and maintain it.

The GAO figures have sent NASA officials into orbit. In a letter printed in the GAO report, Noel Hinners, Associate NASA Administrator for Space Science, charged that "presenting this eclectic array of cost data as a life-cycle cost estimate for the space telescope is misleading". In an interview with *Nature* last week, Hinners said that NASA is still estimating that the development cost for the LST will be about \$435 million, and that the operations costs will be about \$10-\$15 million a year. The operating estimates do not include shuttle launch and refurbishment, he acknowledged, because it is not known how frequently the telescope will be visited for maintenance.

Hinners argued that the operating cost for the LST will not be much different from the \$10 million it costs to operate a major ground-based facility such as Kitt Peak. "I don't see anybody saying that if Kitt Peak lasts for 100 years it will cost \$1 billion", Hinners wryly observed.

Nevertheless, whatever the accuracy of the GAO figures, the report highlights the fact that the cost of the LST will not end with the launch, and the figure of \$1,400 million is sure to be a powerful weapon in Proxmire's hands. Few people are willing to predict the outcome in the Senate for, although Proxmire has failed to sway his committee against NASA projects in the past, there has been a significant change of membership on his committee this year. Two staunch supporters of the space programme, Lawton Chiles of Florida and Bennett Johnston of Louisiana, have been replaced by James Sasser of Tennessee and Patrick Leahy of Vermont, both of whom are fiscal conservatives. Even if he loses in committee, however, Proxmire is expected to take his fight to the Senate floor.

According to committee sources Proxmire is concentrating on the LST at this stage, and is probably prepared to approve funds for the Jupiter Orbiter Probe (JOP). But the sources

suggest that if Proxmire loses on the LST, he may then turn on the Jupiter project. NASA officials would regard loss of that project as a body blow for the planetary science programme in general and to the Jet Propulsion Laboratory in particular. If both the House and Senate delete funds for the project, there would be no chance to reinstate them in conference committees.

At present, there is only one approved planetary mission under way. That is the so-called Voyager project which involves launching spacecraft in August this year to flit past Jupiter and travel on to Saturn. One of the spacecraft may also be re-targeted to swing past Uranus eight years after launch. Thus, if the JOP is not approved, there would be a major hiatus in the planetary programme, with no projects under development at all. According to NASA officials, up to 300 people would be laid off at the JPL, which is now the focus of NASA's planetary work. It should be noted that if the 1982 launch date is missed, there would not be another good opportunity until 1987, because Jupiter will be too far away.

Again, NASA officials argue that if the JOP is killed, planetary science teams would be broken up, and the continuity between programmes would be lost. The technology used on the Pioneer Venus probes would be adapted to the JOP mission, and the JOP spacecraft technology would in turn be used on the planned out-of-ecliptic mission. If there is a major disruption in the planetary programme, "we would lose that inheritance from one mission to the next", Hinners says.

NASA officials are taking those arguments to Senators now in the hope of building support for the efforts. Though the prospects are difficult to assess, it is expected that the LST will scrape through in the Senate, and that the Senate will also approve some funds for the JOP. If those decisions are upheld in the conference committee, NASA would be able to start work on JOP next year, and avoid major layoffs.

Finally, it should be noted that the reason why these projects are deemed especially crucial this year is because some space science projects have been squeezed out of NASA's budget during the past four years to accommodate funding for the space shuttle. Space scientists have been assuming, however, that when funding for the shuttle begins to run down, more money would be made available for space science. Next year is the first year of reduced shuttle funding, but science projects are still at the front of the firing line. □

DNA bills drafted

UNDER intense lobbying from a number of scientists, committee staff members in the House and Senate have put together draft versions of legislation to control recombinant DNA research in the United States. Though there are still plenty of opportunities for the drafts to be altered by the committees themselves, major differences are shaping up in the approaches embodied in the House and Senate versions. The draft Senate bill, in particular, is causing consternation among many scientists.

The House bill has already been approved in principle by the health subcommittee of the House Commerce committee, and members of the subcommittee are expected to meet next week to approve the final wording. It will then go to the full committee for approval before being sent to the floor of the House. The Senate version has not progressed that far. It has been drafted by staff members of the health subcommittee, though it is said to reflect the views of the subcommittee chairman Edward Kennedy, and it will not be considered by the committee itself until next week at the earliest.

The House draft would require the Secretary of Health, Education and Welfare (HEW) to draw up new recombinant DNA regulations, with the advice of a top-level advisory committee, and to licence facilities where such experiments are to be conducted. The bill would leave much of the implication of the regulations, including the granting of most licences, to local biohazards committees, however. Consisting mostly of scientists, the committees would include lay members and representatives of local communities. The Senate version, on the other hand, would establish an eleven-member commission in HEW to draft regulations and issue licences for facilities and for individual experiments. Both versions imply that, until new regulations are adopted, guidelines issued last year by the National Institutes of Health would be given the force of law.

The Senate approach has come under heavy fire by scientists, most conspicuously in a resolution approved late last month by the National Academy of Sciences, for fear that it would lead to bureaucratic delays and subject the research to inordinate red tape.

One of the most controversial issues in the debate on federal legislation has been whether state and local governments should be allowed to establish local controls which are more strict than the federal regulations. The draft House bill would allow them to do so only if they can prove to the Secretary of HEW that there are compelling local reasons for stricter controls, or that the federal regulations are not strict enough to protect public health, requirements which come close to making the federal controls paramount. In the Senate, Kennedy is said to favour allowing state governments to set stricter controls, though some other members of his subcommittee favour the House approach and agreement has yet to be reached.

BRITAIN

Waiting for summer

Chris Sherwell reports on latest developments in Britain's nuclear power debate, now picking up again

THE issue continues to insinuate itself; only its locus changes. The excitement over nuclear power in recent weeks—since President Carter announced his policy—has been generated in various international forums, notably in London at the meeting of the so-called nuclear suppliers group and at the Downing Street economic summit, and in Salzburg, where two conferences were held in quick succession.

Now the issue is coming home. The second Salzburg conference had not even ended late last week before British experts were called away to attend one of the two meetings which took place in London at the weekend on domestic nuclear policy. The one bringing the experts back was called by Mr Anthony Wedgwood Benn, the UK Secretary of State for Energy, and was held in secret. Ironically, the other meeting, held in public and involving hundreds of largely lay people, attracted far less publicity. It was organised by Friends of the Earth (FoE).

Called a conference for a non-nuclear world, the FoE meeting produced a mostly young audience whose views on nuclear power were much as expected: negative. Their enthusiasm was fanned by remarks from two MPs, Robin Cook and Nigel Forman. Cook urged local groups to latch on to nuclear-related local issues and to exploit them relentlessly; Forman's advice was simple—citing a recent opinion poll, he said "secure yourself the help of a friendly scientist".

Neither man was invited to Benn's meeting, though the Commons was represented, through the chairman of the Select Committee on Science and Technology, Arthur Palmer. Indeed, many of the 30 or more people meeting in the seclusion of the Civil Service College at Sunningdale were favourably disposed to nuclear power. They included Sir John Hill of the UKAEA, Con Allday of BNFL, Ned Franklin of the National Nuclear Corporation (NNC), and Frank Tombs of the Electricity Council. Others present included Sir George Porter, Sir Alan Cottrell, Lord Todd, Sir Herman Bondi, Sir Kenneth Berrill, Lord Balogh, Dr Walter Marshall and Sir Brian Flowers—altogether a high-powered line-up.

That not all were so disposed—Walter Patterson of FoE was there to

put the alternative view—at least said something about Mr Benn's desire to hear all sides of opinion. And opinions were what he was there to hear: it was not a meeting to take decisions; rather, it was a meeting that anticipated them.

After months if not years of the public debate he has himself spurred on, Mr Benn is now coming under increasing pressure to call a halt to it all and to start, in the words of one participant at Sunningdale, doing what he was elected to do—take decisions. With the inquiry on an oxide fuel reprocessing plant at Windscale for BNFL due to begin on 14 June, that controversial issue is temporarily out of his hands. But two others await action.

One is on the choice of nuclear reactor for Britain, an issue which goes back to at least 1974, when everyone thought it was finally agreed that the Steam Generating Heavy Water Reactor (SGHWR) would be the country's next generation reactor. The issue was reopened last year, and decision-time has again arrived. The choice is between the SGHWR, the Advanced Gas-Cooled Reactor (AGR), a British product now apparently performing well after teething troubles, and the Pressurised Water Reactors (PWR) which now dominate the world market.

Press reports over the past couple of months have revealed a tilt in favour of the AGR. Mr Benn is himself awaiting a detailed report from the National Nuclear Corporation on the

three types of reactor, and has advised its compilers of the sort of questions he wants answered. He is also awaiting a report from the National Nuclear Inspectorate on the safety of PWRs. Both reports are due out soon, probably next month.

At the weekend meeting Sir Brian Flowers, the former chairman of the Royal Commission whose report last year on nuclear power became the layman's *locus classicus*, urged that a choice be made. That report, the government's response to which is also due to be published shortly, escalated the debate on the fast breeder, which is the subject of Mr Benn's other decision. Having originally promised a decision last autumn and then stated earlier this year that a decision yet is not necessary, Mr Benn is now talking about the coming autumn as a deadline. The decision is on whether to go ahead with a demonstration commercial fast breeder (CFR1) at Dounreay, and the industry, notably in the form of Sir John Hill, is saying that there is no time to waste.

All the suggestions of urgency, and there are now many, do not derive from an immediate need for energy. The worry is that the growing surplus Britain is now acquiring will be lost by the 1990s, and that long lead times make action now essential if nuclear power is to play its allotted role alongside coal and conservation as one of the principal originators of Britain's supplies in the 1990s. That nuclear power is destined to do that was apparently agreed at Sunningdale; that it should entail a full nuclear cycle and

After Moscow, the world

EVERYONE knows the world market for energy has been transformed in this decade. Not everyone appreciates that the world market for energy (and every other commodity) could be transformed completely and even more radically within the next couple of decades if China and the USSR, separately or together, produce the sort of economic growth that countries like Japan or Germany have experienced.

One man who does claim to appreciate the problem is Britain's Secretary of State for Energy, Mr Anthony Wedgwood Benn. Last week he spent two full days in Moscow and came away enthralled. His purpose was to paint in the detail of the 'eastern perspective' on the global energy canvas that he likes to speak about. To get the other perspectives—west, north and south—he has already visited Washington, Norway and Saudi Arabia. Having assimilated all that, his next step will come at the EEC Council of Energy Ministers in the middle of June, when he reports back.

His tentative conclusion is that there is a need for a world energy policy.

What this means precisely is not clear: to many, a world policy implies a world government to implement it; to Mr Benn it means at the very least having information on world supply and demand for energy. He cites almost scornfully a book out this week on global energy prospects to the end of the century which takes no account of countries like China or the Soviet Union.

So what did he learn in Moscow? That the USSR is the world's biggest energy producer. That the Russians hope to use still higher voltage electricity transmission. That they are interested in Britain's offshore oil technology. That they do not dump medium-level nuclear waste into the sea. And that they are very keen to hear assessments of US nuclear policy.

Mr Benn also received one "small rebuke". Each year, he was told, 100 US scientists visited the USSR, and 100 from the USSR visited the States. For France the figure was 70. For Britain over a three-year period, however, the figure was only 50.

Chris Sherwell

a system of fast breeders was a matter of greater dispute.

From all accounts the participants agreed that if reprocessing was to be done at all, it could be done most reliably at Windscale. There was also fairly wide agreement that technically speaking enough could be done to combat the threat of proliferation, but that the problem of public acceptability—the all-important political dimension

—would remain. Had any of the participants retained doubts on that score, the other weekend meeting might have helped to dispel them.

Now, with few new arguments to present or to hear, everyone with any influence over the shape of Britain's nuclear policy is hoping for just one thing: that with decisions ultimately a matter only of a signature, Mr Benn will have a restful summer. □

SWITZERLAND

Guidelines emerge

Rosmarie Waldner reports from Zurich on Swiss moves to produce guidelines for genetic manipulation experiments

A SWISS Academy of Medical Sciences Committee founded in 1975, the Commission for Experimental Genetics, recently took the first step towards regulating genetic manipulation in Switzerland when it sent a circular to all researchers in the field of recombinant DNA recommending observance of the guidelines laid down by the US National Institutes of Health (NIH), Switzerland. It sent a circular to the guidelines issued for NIH researchers in June last year. The Swiss guidelines, however, are not legally binding, although they are considered to be obligatory for the researcher. The committee also wants research projects to be registered, in line with the recommendations of the Strasbourg-based European Science Foundation (ESF).

The commission, under the presidency of Professor Werner Arber of the Biozentrum of the University of Basle, is of the opinion that "things as they stand at present do not justify issuing an official order. The caution expected of researchers in this field, with its legal basis in the Epidemic Law, should ensure general observance of the recommended guidelines". The Swiss Epidemic Law regulates measures in connection with infectious diseases and is one of the few laws in the field of public health valid in all parts of Switzerland; public health, not being a federal matter, is under the jurisdiction of Switzerland's 25 cantons.

At their annual conference held in early April the Swiss Society for Cellular and Molecular Biology discussed the guidelines and voted overwhelmingly in favour in them. However, some speakers demanded that the guidelines be made legally binding and that the public should be brought into the discussion. Altogether six laboratories at the universities of Basle, Geneva and Zurich and at the im-

munology institute of the pharmaceutical company Hoffman-La Roche in Basle are working with recombinant DNA.

The commission is available for advice or will arrange for expert assistance to be provided by the European Molecular Biology Organisation (EMBO) in Heidelberg if local researchers have any doubts about the correct classification of a research project within the various criteria of the NIH guidelines. It is also available for general consultation and for the interpretation of the NIH guidelines. As Professor Arber stresses, the commission does not consider the NIH guidelines adopted in Switzerland as unalterable; it wants to keep a constant watch and make changes (even if these deviated from the NIH guidelines) if this was considered necessary.

When registering, researchers responsible for a project must announce their intentions and state the precautionary measures taken. "The committee considers the observance of these measures, registration and the provision of correct information to colleagues to be part of the duty of each and every researcher", the circular states. Research heads and heads of department at universities and other public and private institutions have been requested to support the commission's efforts.

The Swiss National Fund for the Promotion of Scientific Research particularly wants to promote the research in Switzerland. When it comes to the allocation of research funds, however, it insists on observance of the guidelines. The fund has mentioned the possibility of becoming involved in the establishment of a special safety (P4) laboratory. This project is expected to cost SF1.5 million.

The Swiss press has welcomed the guidelines, but there have been complaints that decisions concerning research with such far-reaching consequences should have been made in camera—the commission has no lay representatives, nor even experts from

W. GERMANY

Breeder hold-up

UNDER increasing pressure from environmental protectionists, the West German government has called a temporary halt to research and development on the fast breeder reactor. Last week, Dr Hans Matthöfer, the West German Minister for Science and Technology, announced that no more money was to be spent on R&D for the fast breeder until questions raised by the Social Democrats on the safety of fast breeder technology and the proliferation of nuclear weapons through the spread of plutonium had been considered by the Bundestag.

This means a bar on spending whatever has not yet been committed of the DM122 million set aside for fast breeder R&D under the government's medium term energy plan. Work already contracted, however, such as the prototype liquid metal fast breeder at Kalkar, will go ahead. It will be financed from that portion of the DM227 million fast breeder programme not devoted to research. Other projects unlikely to be axed are West Germany's collaboration in the construction of the French Superphénix and the fabrication plant for fast-breeder fuel elements which is already in operation.

Prior to the latest announcement discussion about the further development of breeder reactors in West Germany was becoming livelier. In the Social Democratic party above all there was increasing resistance to further financing of R&D work. The Ministry for Research and Technology had explained in detail to the Bundestag the pros and cons of the evolution of the fast breeder—it seems unsuccessfully.

Germany began development of the breeder in 1960—researchers got their early experience through participation in the construction of the American experimental reactor SEFOR. The 300 MW breeder at Kalkar is a German-Belgian-Dutch joint project due to be completed in 1982. Within the framework of the German-French agreement on Superphénix, Germany contributes 16% of the cost via electricity supply undertakings.

When the West German government presented its energy research programme at the end of April, Dr Matthöfer claimed that because of public resistance, his ministry had felt obliged not to balance the programme as much in favour of nuclear power as it had originally intended. It had been necessary to cut the target of 45,000 MW of nuclear power by 1985 to 30,000 MW. Nevertheless, the energy research programme puts greatest emphasis on nuclear power: out of the DM6,200 million to be spent on energy up to 1980, DM4,500 million was to go on nuclear energy. □

fields other than biology and medicine. The hope was expressed that parliamentarians would soon be roused: questions were put in parliament as early as two years ago; since then there has been silence on the subject.

IN BRIEF

US nuclear snag

President Carter's plans to defer nuclear fuel reprocessing and to turn down the breeder reactor programme have hit a snag in the US House of Representatives and they could face a stiff challenge in the Senate. Last week, the House Committee on Science and Technology voted 38 to 0 to keep funds for a demonstration breeder reactor in the budget for the Energy Research and Development Administration (ERDA), but with the understanding that the committee will investigate the matter further and vote on the funds again before sending the ERDA budget bill to the House floor.

Committee sources note that the vote was a procedural measure which doesn't necessarily indicate the committee's final view, though they suggest that the prevailing opinion among committee members seems at present to favour rejecting Carter's request to cancel the demonstration project. In the Senate, Senator Frank Church, who heads a key energy subcommittee, said in a speech at MIT earlier this month that Carter's plutonium strategy will not work because other countries are unlikely to follow suit. In a later interview with the *Washington Post*, Church said that the United States should continue with the breeder project and with reprocessing to avoid

"nuclear isolationism". The opposition to Carter's plans virtually guarantees that there will be a major debate on plutonium policy on the floor of the House and the Senate this summer.

Pipeline report

Controversial recommendations from a Canadian judge regarding proposed pipelines stretching between the Arctic and Southern Canada and the USA will not be acted upon at least until a second report is published, probably in the summer. The judge, Thomas Berger, reported on the ecological and social implications of the proposal last week, and recommended a morator-

THE heavy veils of secrecy that the French are drawing over the details of their method of enriching uranium to reactor- but not to weapons-grade make it difficult to evaluate their claims. But if their recently revealed chemical enrichment technique stands up to full scale testing and is as tamper-proof as they suggest, cheap enrichment plant should be available in the 1990s to many countries which might not have been considered responsible enough to own it.

The French announcement, at the recent IAEA nuclear fuel cycle conference in Salzburg, was neatly timed to coincide with the economic summit in London. With an undoubted shortage of enrichment plants the new process seems to offer the possibility of meeting the need without increasing the risk of proliferation. It is not clear, however, whether such enrichment facilities would allow the use of the fast breeder reactor to be postponed; that depends on whether, in the absence of the new technique, the use of uranium in thermal reactors would be limited by a shortage of enrichment facilities or by the scarcity of uranium itself—which in turn will be determined by the economics of extraction.

Enrichment used to receive a great deal of attention as a process encouraging nuclear proliferation. Concern has since focused on reprocessing the spent fuel. Natural uranium, containing 99.3% ^{238}U and 0.7% fissile ^{235}U , must be enriched to 3–4% ^{235}U for use in American LWRs and 2% for the British AGRs. The Canadian CANDU and the British Magnox reactors use natural uranium, as oxide and metal respectively. The sensitive aspect of enrichment is that an enrichment plant may be arranged so that enrichment to over 90% instead of 2–4% is

achieved, enough to make a uranium bomb.

Reprocessing offers a similar opportunity, but here to make a plutonium bomb. The civil purpose of reprocessing spent reactor fuel—that is, separating plutonium from uranium and radioactive wastes—is to use the

Power sans bombs

Enrichment cascade (Fotosmit)

BACKGROUNDER

plutonium to fuel more reactors and especially the fast breeder. The French development could make it more difficult to get hold of uranium bombs, but would not affect the ease of access to plutonium bombs.

The main enrichment process in current use is gaseous diffusion, uranium hexafluoride being diffused through a porous membrane. The lighter ^{235}U atoms diffuse slightly more readily than the ^{238}U and enrichment is achieved by a large number of stages in cascade. Compression and cooling at each stage mean that energy consumption is very high (6% of the energy generated by PWR fuel). In the newer ultracentrifugation process, favoured by the British, Germans and Dutch, the

diffuser is replaced by a centrifuge. The capital costs of centrifugation are very high but the electricity consumption is only 10% that of diffusion.

The chemical exchange process announced by the French is said to have the advantages of low energy consumption, rather simple technology and suitability for small-scale plants. Separation of the two uranium isotopes based on the different rates with which molecules containing them react has been explored in the past, but had been largely discounted by most workers because the very small difference in chemical reaction rate only allows extremely slow separation.

The French breakthrough apparently lies in finding two uranium compounds which undergo reactions whose rates are more markedly affected by the uranium isotope. What the molecules are has not been revealed. The enrichment process is still rather slow but this is the main safeguard against bomb manufacture; while the period of two years needed to produce 3% enriched uranium by the chemical method seems industrially feasible, it would take fully 30 years to produce bomb-grade plutonium. By contrast, bomb-grade material can be prepared in two years by gaseous diffusion and one day by ultracentrifugation.

The French say two other safeguards are built into their process. One is that the process cannot be arranged in cascades (which can, at least in theory, be manipulated to produce a small quantity of 90% enriched fuel instead of a larger quantity of 3% enriched fuel). Furthermore, if too much enrichment is attempted, the uranium risks going critical. This seems to be because a liquid phase is involved, and in a liquid there is the risk of local concentrations of very high enrichment.

ium, to the chagrin of industrial interests. A second report on the economic need for the pipeline is awaited from the Canadian National Energy Board, which regulates the oil and gas industries and is still holding hearings.

USSR action on seminar

Professor Mark Azbel has been ordered by the Soviet authorities to cease holding the 'Sunday Seminars' for refusenik scientists. The seminars have been held regularly for five years, and only a month ago Professor Azbel was given a once-off permission to hold a special anniversary session—the first time that the authorities openly acknowledged the existence of the seminars.

Within the past three weeks, Pro-

fessor Azbel has been summoned three times to the Lubyanka and Lefortovo prisons for interrogation. He was obliged to sign an undertaking not to reveal the contents of the investigation. It is known, however, that it related to his association with Anatolii Shcharanskii, the unofficial 'press-agent' of the seminar group at present held for investigation for alleged contact with the CIA.

Last week Dr Viktor Brailovskii and Dr Veniamin Fain, who are among the senior members of the group, were also called in for interrogation.

The most recent message received from Professor Azbel was that the authorities are striking at the 'Professorate'. Previous action against refusenik scientists has been aimed at the lower echelons.

NPL's new director

Dr Paul Dean is to take over as director of the National Physical Laboratory (NPL) on 1 October. He will succeed Sir Iuean Maddock, who has been acting director since giving up his appointment as chief scientist at the Department of Industry at the end of last March. Dr John Dunworth, the previous permanent director, retired last June; he joined the NPL as deputy director in 1962 and became responsible for the laboratory in 1964. Dean joined the laboratory in 1957, and will be moving from the Department of Industry's headquarters, where he was head of the Space and Air Research division. He was also Head of the Research and Development Contractors division.

THEY came in busloads from as far away as Minnesota. They wore pro-laetrile buttons. They were prepared to pack the hearing room, to applaud wildly at the inflammatory oratory of their leaders, and to boo, hiss and interrupt when members of the 'medical establishment' warned them of the uselessness of laetrile in cancer therapy.

The occasion was the Food and Drug Administration (FDA) Administrative Rulemaking Hearing on Laetrile, held in Kansas City, Missouri at the beginning of May. To 'bend over backwards', the FDA had talks by the laetrile crusaders, following opening remarks by the presiding officer. My experience with hearings led me to know that the television cameras and reporters would be present at the morning session, and they would depart at noon, leaving the opponents of laetrile without media coverage, just as the opponents of banning DDT were treated in 1969.

Efforts at appeasement always fail. At 8 am on the first day the laetrile pushers called a press conference that was largely devoted to rhetoric against the FDA and allegations that the hearings were a "kangaroo court". I asked if the laetrile supporters had been given the opportunity to speak at the hearings. The answer was, necessarily, "yes", but a woman hastened to my side and hissed in my ear that if I interrupted their press conference with any more questions, she would call the hotel manager and have me removed forcibly from the room. I managed to avoid this fate when I asked my next question, by alleging that I was a reporter for *Nature*. I requested any scientific literature reference, even one, to substantiate the claim that laetrile is

vitamin B17. I was told "wait until tomorrow".

During the hearings, professors of medicine were jeered at and heckled. Advocates of laetrile, shouting and declaiming in the manner of a

Quackery triumph

THOMAS H. JUKES

religious revival meeting, were wildly applauded as they testified to their "cures". The audience was ecstatic, as well it might be. Bills to legalise laetrile without even defining what laetrile actually is, have just been passed by the legislatures of Alaska, Florida, Indiana and Nevada. The Indiana Bill had successfully overridden the Governor's veto. The Nevada bill includes a 10% cut on laetrile sale for the State Treasury.

The publication of the laetrile pushers, *The Choice*, was bursting with exultant information. It contained advertisements for "Reverend Clifford Oden's stirring call to faith in God and vitamin B17", for a new

water distiller that would remove fluoride from drinking water, and for a book on "chelation therapy in the killer diseases". The publication informed its readers that "efforts to decriminalise laetrile use in Texas surged into the forefront where 150 members of the lower house shouted their approval of the freedom of choice bill and stood up and cheered after the unanimous vote was delivered". One of the photographs showed two 'Wisconsin committee leaders' carrying "23,000 names on signatures" in support of pro-laetrile bills introduced into the Wisconsin legislature; another was of Gloria Swanson telling her health philosophy and her personal victory over a tumour.

The pro-laetrile campaign is administering a crushing defeat to science and rationality. Undoubtedly it is well-financed. A Californian 'laetrile physician' was indicted on charges including one of depositing \$2,500,000 in California banks, May 1973 to August 1975. His licence was revoked for "gross negligence and incompetence", 29 November, 1976.

The technique for arousing support is an appeal to revolt against authority, bureaucracy and the 'medical establishment'. Political action is effected by writing letters to legislators. This procedure was overwhelmingly successful with the Proxmire Bill in the US Senate 1975, specifically directed against the authority of the FDA.

Things fall apart; the centre cannot hold; Mere anarchy is loosed upon the world, The blood-dimmed tide is loosed, and everywhere

The ceremony of innocence is doomed; The best lack all conviction, while the worst

Are full of passionate intensity.

Technology and politics

SIR,—After making several criticisms of *The Technology of Political Control*, your editorial (14 April, page 577) ends with a conclusion which displays an apparent ignorance of the structural basis of control. Although I accept the admirable sentiment that, "the real need is for scientists who are involved in military and police research to be able to speak up when they see the balance shifting in an unsavoury direction," the realities of the situation in practice make this suggestion naive. Given the essence and ramifications of such work, it is likely to be covered under the Official Secrets Act and thus government researchers in these areas are forbidden from making their work public.

The writers of the *New Technology of Repression* are among the few scientists who can present unrestricted information on this topic in an informed way. Yet, as the recent search of my house and university room by the Special Branch indicate; no-one who researches in this controversial area can be assured of freedom from interference. It must not be forgotten that scientists are also numbered amongst the victims of the technologies of political control.

Yours faithfully,
STEVE WRIGHT

'The Selfish Gene'

SIR,—It is no great surprise that W. D. Hamilton has written such an intemperate letter about my review of *The Selfish Gene* (12 May, page 102). Despite his considerable concrete contribution to the theory of kin selection, Dr Hamilton has himself given way to the lure of unscientific speculation on the biological basis of human history, and is responsible for his fair share of vulgar Darwinising. I will comment on three points in his letter that have appeared frequently in replies to criticisms such as mine. First, despite a string of pejorative comments on my objectivity and the quality of my analysis not a single instance is offered of my mistaken analysis. The reader will be as suspicious as I am that "It would be easy to defend the book and reply to the review point by point" when not a word of defence is offered, but

only 350 words of angry invective.

Second, with great modesty, Dr Hamilton compares himself and his fellow sociobiologists to Darwin, and Dr Dawkins to Huxley. Other biological determinists have recently, in their apologies, compared themselves to Galileo! Everyone with a pet theory thinks himself a Darwin or Galileo, the moment his errors are criticised. But my criticism of Dawkins comes not from an outraged church establishment, but from the solid accumulation of the science of population genetics. The real problem in scientific progress is to distinguish those with a revolutionary new insight into nature from crackpots with delusions of grandeur. Self-advertisement is poor evidence.

Finally, Dr Hamilton confesses that he feels little concern about the basic epistemological questions that are at issue. Rather he feels a great warmth about the "spirit" of Dr Dawkins' book and the "science" it describes. But it is precisely the substitution of "spirit" for the elements of logical thought that makes *The Selfish Gene* such a worthless piece of vulgarisation. What is revealed by Dr Hamilton's letter is that Dawkins' errors are not simply those of an overenthusiastic but naive populariser. They are an accurate reflection, it seems, of the quality of thought of the sociobiologists themselves. We will surely not understand the nature of the world by an excess of spirit and a deficiency of hard thought. Dr Hamilton, Bishop Wilberforce would have been proud of you.

Yours faithfully,
R. C. LEWONTIN

Scotland get its share

SIR,—It is difficult to know whether the letter by D. N. M. Hamilton (28 April, page 770) is meant as a serious contribution or as a joke. If he seriously thinks that those who advise the Medical Research Council state that the Scots believe that the people in London are more deserving of money for research than are the research workers in Scotland, I should have thought he would have drawn this to the attention of the MRC directly and suggested most strongly that they change their advisers.

My department has been generously

supported and assisted by the MRC on the basis of projects submitted to them, and in my many conversations with the administrators in the MRC, I have been left in no doubt that there is considerable regard for the immense amount of scientific activity that is conducted in the scientific centres in Scotland. At no time during any conversation have I been left with the impression that institutions outside London—and particularly those North of the border—are regarded as poor relations. If there should at any time appear to be a departure from the strict correlation between the percentage of population and percentage of MRC money spent in a given area, I suggest that the remedy lies with Dr Hamilton and others who may think with him, to produce research and other programmes which are judged to be well worth supporting from the limited funds which are available to the various grant-giving bodies.

I am not an adviser to the MRC, nor has my view on the distribution of their funds ever been sought, and, in common with the vast majority of research workers, I also have had programmes rejected, but one keeps trying.

Yours faithfully,
P. J. HEALD

A plea for hyphens

SIR,—At the risk of sounding pedantic I want to make a plea for a return to the sound practice of writing a hyphen in compound words used adjectivally. Today's general practice of omitting the hyphen in such adjectives as 'hormone-induced' and 'temperature-sensitive' is sheer sloppiness and, more seriously, often leads to ambiguity. That almost everyone does it is no excuse. Gowers, to whom lip-service is still being paid, gives very sound advice on the matter of hyphens on page 183-84 of *The Complete Plain Words* (HMSO, London 1973). So do several English and American style manuals and dictionaries.

Yours faithfully,
J. FABER

The structure of transcribing chromatin

from H. R. Matthews

THE bulk of eukaryotic chromatin is organised in a repeating subunit structure. Each subunit or nucleosome contains a core of two each of the histones H2A, H2B, H3 and H4 with about 195 base pairs of DNA folded or coiled outside the histones into about $\frac{1}{2}$ of its extended, B form, length. The nucleosome can be reconstituted from DNA and histones alone and in this structure the DNA is not available for transcription, at least not by *E. coli* RNA polymerase. Tissue specific non-histone proteins can modify the DNA and histone structure to give active chromatin where the DNA is accessible to RNA polymerase (see for example Paul & Gilmour *J. molec. Biol.* **34**, 305; 1968). The same situation probably applies *in vivo* and so although the bulk of the DNA in chromatin is coiled in nucleosomes what is the structure of active DNA?

Isolation of active chromatin is an important step towards studying its structure although this road is littered with scientific retractions. The other two approaches are to look for active genes in nucleosomes and to study chromatin in the electron microscope. J. M. Gottesfeld and his colleagues have described a promising approach to the preparation of an active chromatin component which involves digestion of total chromatin with spleen DNase II followed by precipitation of inactive chromatin with $MgCl_2$. The Mg^{2+} -soluble chromatin has been found to contain nascent RNA, to include DNA sequences that are known to be transcribed, but to exclude inactive DNA sequences. This has been shown in Friend cells which can be stimulated to synthesise globin messenger RNA. Mg^{2+} -soluble chromatin from unstimulated Friend cells does not contain globin genes whereas Mg^{2+} -soluble chromatin from the stimulated cells does. Moreover, in a range of cell types the amount of Mg^{2+} -soluble chromatin correlates with the overall transcriptional activity. The Mg^{2+} -soluble chromatin displays the same DNA

repeat length, 198 base pairs, as bulk chromatin which implies that the DNA repeat is a property of a class of chromatin structures rather than of a unique structure. However, complete nucleosomes from the Mg^{2+} -soluble chromatin sediment faster than nucleosomes from the bulk chromatin. Mg^{2+} -soluble nucleosomes contain RNA and non-histone proteins as well as histones and are particularly sensitive to pancreatic DNase I. Preliminary experiments suggest that Mg^{2+} -soluble nucleosomes contain regions of unstacked DNA, unlike the bulk nucleosomes (Gottesfeld, Royal Society Discussion Meeting, 1977). Under the action of RNase the Mg^{2+} -soluble nucleosomes change into the bulk nucleosome structure so Gottesfeld's results are interpreted to mean that active chromatin is in a different structure from bulk chromatin but that the active structure readily changes to the bulk structure.

In the second approach bulk nucleosomes are prepared and their DNA is hybridised to cellular mRNAs to try to detect active genes. Considerable hybridisation is observed suggesting that active DNA is indeed in the bulk nucleosome structure, but these experiments are also open to the alternative explanation that in the cell population only some copies of the genes tested are active at a given time and the hybridisation could be due to nucleosomes released from inactive sequences. Reeves (*Science* **194**, 529; 1976) suggests this may be at least partly the case from his data on the proportion of rRNA genes found in bulk nucleosomes from cells with different rates of rRNA synthesis. As the table shows, rRNA genes are under-represented in nucleosomes from cells where rRNA synthesis is high.

The rRNA genes are relatively easy

to study because they are normally highly active and reiterated but in the past few years the availability of pure eukaryote mRNAs and reverse transcriptase (RNA-dependent DNA polymerase) has allowed studies of genes such as those for globin and ovalbumin which occur in only one or a few copies per genome. These genes are also found in bulk DNA from nucleosomes so they also exist in the nucleosome structure or in a closely related structure.

Bulk nucleosomes are prepared with micrococcal nuclease which produces double-strand breaks in DNA. Another nuclease, DNase I, produces single strand breaks at 10 base-pair intervals in DNA in chromatin to give products that are of single strand lengths 20, 30, 40 . . . 160 or more bases when analysed under denaturing conditions. Weintraub and Groudine (*Science* **193**, 848; 1976) and G  rel and Axel (*Proc. natn. Acad. Sci. U.S.A.* **73**, 3966; 1976) have studied the digestion of the globin and ovalbumin genes respectively. The globin gene is highly sensitive to digestion by DNase I in adult erythrocytes but in fibroblasts where it is inactive the globin gene is less sensitive, as is the bulk of the DNA. The differential sensitivity was confirmed in different cells for the ovalbumin gene. DNA complementary to mRNA was used as a probe for the presence of ovalbumin genes in DNase I digests of liver nuclei where the ovalbumin gene is not expressed, and in DNase I digests of oviduct nuclei where about 75% of the ovalbumin genes are active. These important experiments show that active genes are in a different structure from the bulk of the DNA and from inactive genes although other data suggest the 'active' structure must be closely related to the bulk nucleosome structure.

<i>Xenopus laevis</i> cells	Complement of rRNA genes	Rate of rRNA synthesis per gene	% rRNA genes in bulk nucleosome DNA
Adult erythrocytes	+ / +	Minimal	86
Log phase embryonic tissue culture cells	+ / +	Normal	72
Stage 46 larvae	0 / +	Maximal	60

Electron microscopists were involved at the very beginning of the discovery of nucleosomes. What can they tell us about the structure of active chromatin? Chromatin can be seen after spreading by the Miller technique and the nucleosome structure survives although some stretching of the DNA between nucleosome cores can occur. In chromatin from nucleoli that are actively synthesising rRNA the nascent RNA molecules are packed very closely together in association with spheres of 10 nm diameter along the DNA. Are these spheres RNA polymerase complexes or nucleosomes? W. W. Francke's group (Scheer *et al.* *Chromosoma* **60**, 147; 1977) have measured the length of the transcription unit in pictures of active rDNA and compared it with the length of the largest RNA product that can be isolated. If this is the primary transcript then the comparison shows that active rDNA must be extended in the B form and not packed into nucleosomes. A further correlation has been noted between the total rDNA repeat as measured along active chromatin and

as determined by restriction nuclease analysis, which implies that the non-transcribed spacer is also not in nucleosomes. These are very striking results but some other electron microscopists, notably McKnight and Miller (ICN-UCLA Symposium on Molecular Human Cytogenetics, 1977) have electron microscope data which they interpret as showing the presence of nucleosomes on active chromatin. More work is needed to resolve the apparent disagreement. The electron microscope appearance of active chromatin may depend on how closely packed the RNA polymerase complexes are along the DNA or, if the active structure is easily converted to the bulk nucleosome structure and *vice versa*, then the living state may be a dynamic equilibrium which can be 'frozen' in different ways by different techniques.

Study of the structure of active chromatin is clearly at a very early stage but it is already fascinating to piece together the data from different approaches and we can look forward to more exciting progress very soon.

example the review articles in the *Sunday NY Times*, sect. 4, page 6, 13 March; 1977). An earlier report of a panel set up by the US National Academy of Sciences, *More Water for Arid Lands* (NAS, Washington, DC; 1974), gives an excellent survey of water practices, both very new and very old, which enable the agricultural potential of arid lands to be realised.

Ancient solutions

Ancient desert dwellers collected rain by redirecting water running down hill slopes into fields or cisterns. Such agriculture was developed almost 4,000 years ago, and in the Middle East it permitted crop production on lands receiving as little as 100 mm average annual rainfall, thus sustaining agricultural civilisations in desert regions that today support only a small human population and produce few crops. In the Negev, traces of the Nabatean inhabitants remain in the rock walls they built along contours of hills to convey rainwater to lower lying fields, and in the gravel they cleared (piling it in mounds or strips) in order to bare the loess-like soils that form a crust when wet, increasing run-off. Modern versions of this latter technique use silicones, latexes, asphalt and wax to help make soils water-repellent and promote run-off. Contemporary estimates are that rainwater harvesting is possible in areas with as little as 50–80 mm average annual rainfall, although a water-harvesting catchment in Israel yielded a usable run-off in a year with only 24 mm of rain.

A variant form of rainwater harvesting is to build terraces or low walls on floodplains in order to catch and spread the flash floods that result from short, intense storms. These and other techniques have been developed by biologists and archaeologists at the Wadi Mashash, a run-off agriculture training centre in the Negev that serves trainees from arid lands all over the world. A more full account is given by Evenari *et al.* in *The Negev: The Challenge of a Desert* (Harvard University Press, 1971).

About 3,000 years ago the Persians dug qanats to bring mountain groundwater to arid plains. A qanat, an ancient Semitic word that is ancestor to "canal", is a gently sloping horizontal tunnel that brings underground water from the higher elevations of an alluvial fan down to the lower parts of the surface; a series of vertical shafts between the ground surface and the tunnel characterise the construction of a qanat, and can be used as wells and for maintenance. The old Persians built qanats on a scale rivalling the great Roman aqueducts. Many are still used, especially in Afghanistan and in Iran,

More water for arid lands

from Robert M. May

If the Earth were stationary, with the Sun circling round it, the global patterns of wind and weather would be simpler. There would be two convection cells, one in each hemisphere, with warm air rising at the equator, moving toward the poles, and then completing the convection pattern by returning at low elevations back toward the equator. The Earth's rotation introduces many complications, and broadly speaking the upshot is three convection cells in each hemisphere: in the first, air rises around the equator and falls back around latitude 30° N and S; the second cell, at intermediate latitudes, joins on, with poleward surface convection; the third cell has cold air falling at the pole and surface movement toward the equator. The interface between the second and third cells is relatively unstable, which contributes to the vagaries of the weather at high latitudes. These broad patterns in air circulation, and related patterns in ocean circulation, have had much influence on human history. (For example, they explain why it took so long for sailing ships to find the east coast of Australia, which was obviously a fateful event.)

As the air rises at the equator, it

expands and cools. In the process, water vapour is "squeezed out" (hence the cloud cover at the equator), and the air convected back to the surface at around 30° N and S latitudes tends to be dry. Mainly as a consequence of this fact, all the world's major deserts lie around $\pm 30^\circ$: in the south, the Kalahari, the Atacama (in Chile), western and central Australia; in the north the Sahara, the Arabian, Gobi, and Punjab deserts, and the Great Basin in the US southwest. This feature shows up in biogeographical patterns. Thus in De Candolle's classification of plant types, the smooth continuum from tropical (megathermic plants) to temperate (mesothermic), boreal (microthermic), and arctic (hekistothermic) zones is interrupted around $\pm 30^\circ$ by the band of xerophilic, or "dry-loving" plants.

As human populations grow, these arid regions pose increasingly difficult problems. Although the ultimate cause is not agreed, many of the world's sand deserts seem to be enlarging, and droughts are contributing to the economic devastation of whole nations. The six drought-stricken Sahelian nations probably provide the best known and most extreme illustration. Against this backdrop, the UN Water Conference met at Mar del Plata, Argentina, in early March (see for

where some 40,000 qanats comprise more than 270,000 km of underground channels supplying 35% of the country's water.

Modern alternatives

Beneath many of the world's deserts are reserves of saline water, which offer possibilities for the irrigation of suitably resistant crops. If leaching and drainage are adequate, water with total dissolved salts in the range 500–1,500 milligrams per litre can be used on all but the most salt-sensitive plants. Water with up to 3,000–5,000 mg l⁻¹ can be used with highly tolerant crops. The most salt-tolerant crop studied so far is Suwanee Bermuda grass, *Cynodon dactylon*, which can tolerate about 12,000 mg l⁻¹. This is still a long way from seawater, which has a total salt content of about 35,000 mg l⁻¹.

Reservoirs and canals in arid lands are subject to heavy evaporation losses. As a proportion of total water stored, such losses involve a surface-to-volume effect, and tend to be relatively most severe for large, shallow reservoirs and ponds. Increasingly ingenious methods are directed at covering the water surface with a barrier that inhibits evaporation: these embrace liquid chemicals, usually based on long slender molecules; waxes that melt in the sun to form a film; or solid blocks of poly-

styrene or other light material. Large reservoirs, lakes, and rivers are still beyond the reach of modern technology because it is very difficult for the evaporation-suppressing system to survive heavy winds, storms and floods.

Evaporation from the soil surface of irrigated crop systems can be similarly reduced by latex, asphalt, oil, gravel, or shredded plastic mulches. Alternatively, modern "trickle irrigation" methods apply small amounts of water at frequent intervals, to a specific site near each plant. Such techniques have proved most effective for permanent tree and vine crops, and for crops grown totally under cover. Trickle irrigation will benefit from technological advances that lower costs and increase reliability and freedom from clogging. Loss of moisture by percolation in sandy soils is a problem that can be ameliorated by producing artificial underground barriers of asphalt or plastic; again the difficulty is the cost.

In a typical plant, only 1% of the water absorbed by the roots is incorporated into the plant cells; the remaining 99% is transpired back into the atmosphere. In selecting and breeding crops suitable for arid lands, clearly one of the major goals is to minimise transpiration. But the choice of appropriate plants is another story (see for example *Nature* 265, 209; 1977). □

Vaccination against virus-induced tumours

from Robin Weiss

VACCINATION against Marek's disease (MD), a lymphoma of chickens, is one of the major success stories in viral oncology. It has aroused interest in the possibility of human vaccination against Epstein-Barr virus (a more dubious matter, I think). Marek's disease is caused by a highly contagious herpesvirus present in the feather-dust (dander) of chickens, and the acute form of the disease used to cause serious commercial loss to the broiler industry. Immunisation of one-day-old chickens with attenuated MD virus or with a related, non-pathogenic virus of turkeys protects the chickens from the disease (*Purchase Cancer Res.* 36, 696; 1976). Precisely how the vaccine strains confer resistance to MD is not understood, and two classes of antigens, virus-specific and tumour-specific, have been recognised. The Marek's tumour-specific antigens (MATSA) are

present on the surface of lymphoma cells, but not on MD virus-infected chick kidney cells which express viral structural antigens.

Inoculation of either killed tumour cells (Powell *Nature* 257, 684; 1975) or live, non-transformed, MD-infected kidney cells (Lesnick & Ross *Int. J. Cancer* 16, 153; 1975) immunises chicks against MD. At the recent symposium on 'Viruses and Cancer' held by the British Association for Cancer Research at Cambridge, Powell reported that he could dissociate anti-tumour immunity and anti-viral immunity to MD by different vaccination procedures. Immunisation of chickens with glutaraldehyde-fixed MD-infected kidney cells elicited humoral antibodies that neutralise the virus, whereas immunisation with fixed lymphoma cells elicited a cell-mediated anti-tumour cell cytotoxicity that does not affect viral replication. Both types of immunisation exerted a protective effect against the development of Marek's lymphomas.

Immunity to tumours caused by

RNA oncoviruses may also be accomplished by either anti-viral or anti-tumour cell activities, and there is much interest in preparing vaccines against feline leukaemia virus (FeLV) and its associated diseases. As with the Marek's disease MATSA antigen, FeLV-induced lymphomas express a cell surface antigen, FOCMA, which appears to be unrelated to the viral envelope glycoprotein, gp70 (Stephenson *et al. Proc. natn. Acad. Sci. U.S.A.* 74, 1219; 1977). Most of the effort in developing FeLV vaccines involves the use of FOCMA as the immunogen.

Recently however, de Noronha *et al. (Nature* 267, 54; 1977) report that cats can be protected from sarcomas induced by feline sarcoma virus (FeSV) when passively immunised with antibodies directed against viral envelope antigens. FeSV is closely related to FeLV and has the advantage for experimental studies of producing sarcomas that are lethal within 4 to 8 weeks of virus inoculation, according to dose. The antibodies were prepared in goats and reacted with either FeLV or murine Friend virus gp70. They neutralise FeLV and FeSV, and are cytotoxic to FeLV-producing cells. By inoculating cats with the goat antibodies after FeSV infection, the development of sarcomas was prevented or those that had already appeared regressed. Schäfer and his colleagues (*Bibliotheca Haematol.* 43, 86; 1975) have previously shown similar passive protection against Friend disease in mice treated with anti-gp70 serum. They propose that antibody-therapy could be widely applied to virus-induced malignancies.

One point usually ignored by investigators of oncovirus immunisation is that the tumours induced by the 'strongly-transforming' viruses grow mainly by infecting and transforming new cells rather than by proliferation of tumour cells. The importance of tumour growth by cell recruitment was clearly demonstrated by Pontén (*Natn. Cancer Inst. Monogr.* 17, 131; 1974) for Rous sarcoma in chickens, and it is also important for the development of Friend spleen foci and of sarcomas induced by FeSV and murine sarcoma virus (MSV). Indeed, spreading infection is necessary even in cultures of non-established embryonic fibroblasts for the appearance of MSV-transformed foci (Hartley & Rowe *Proc. natn. Acad. Sci. U.S.A.* 55, 780; 1966). While the prevention of tumour growth by antiserum to gp70 might be mediated through a cytotoxic effect on the tumour cells, an alternative mechanism may be through neutralisation of virus particles.

Linna *et al. (in Tumor virus infec-*

Robin Weiss is Head of the Department of Viral Oncology at the Imperial Cancer Research Fund, London.

tions and immunity (eds Crowell R. L., Friedman R., & Prier J. E.), University Park Press, Baltimore, 1976)) have shown by using a complex induction system of Rous sarcomas which demands virus rescue from virogenic, non-producing cells, that neo-hatching thymectomy increases the number of sarcomas, whereas bursectomy enhances their rate of growth without affecting tumour frequency. The effects of thymectomy and bursectomy on low-dose sarcoma virus inoculation might prove more illuminating for distinguishing between anti-virus and anti-tumour cell immunity.

With the weakly-transforming oncoviruses, such as the avian lymphoid leukaemia viruses or the murine AKR-Gross virus, tumour growth seems to be largely a consequence of proliferation of one or a few clones of leukaemic cells rather than progressive recruitment. In this situation, once the malignant clone has arisen, virus neutralisation should have no role in tumour control. However, anti-rival antibodies may be important after infection yet before malignant trans-

formation, as they clearly are in natural infection of chickens and cats. Even in mice, which carry the genomes of leukaemogenic viruses in all their cells as endogenous genetic elements, only those strains that produce re-infecting virus, such as AKR and C58, have a high incidence of lymphoma. Thus a humoral response against the virus may be efficacious in preventing lymphoma. Many strains of mice naturally develop humoral antibodies, and a recent paper by Lee, Ihle, and Huebner (*Proc. natn. Acad. Sci. U.S.A.* **74**, 343; 1977) shows that formalin-inactivated virus is suitable for eliciting antibodies to gp70 and p15E, the virus envelope proteins. It will be interesting to see whether such virus-immunised mice are protected against tumours and whether cell cytotoxicity or virus inactivation plays the more important part.

I suspect that both types of immunity will be significant. Their effects may well be synergistic, both in Marek's disease, and in oncovirus-induced leukaemias and sarcomas in chickens, cats and mice. □

smoothly shifts the peak absorption wavelength. The theme of this lecture was in effect the advent of optical absorption engineering, just as Wilson had described the engineering of energy gaps.

A. D. Yoffe (University of Cambridge) spoke about solids with one- or two-dimensional order, with special emphasis on electrical conduction. The tetracyanoplatinates featured again as variants of the chain conductor, but pride of place went to the polymer (SN)_x made by polymerising S₂N₂. This is the first known polymeric superconductor, with $T_c = 0.3$ K; however, at least one pair of long-chain eyebrows was raised in scepticism as to the polymeric status of this material. Attempts are being made to substitute Se for S and As or P for N with a view to improving the superconducting performance. Yoffe went on to discuss MX₂ layer compounds, a large family with M=Ti, Zr, Hf, V, Nb, Ta, Mo or Nb and X=S, Se or Te. These range from insulators through semiconductors to metals and show several kinds of order. Yoffe spent some time on Overhauser's notion of charge density waves which are well exemplified by some of these compounds. The CDW are linked with periodic displacements of atoms in the layers and in turn effect conductivity changes at the critical temperatures. Intercalation of metal atoms, such as K, between the layers can transform a metallic compound into a semiconductor or *vice versa*, and some intercalates turn out to be hard superconductors. There are prospects of developing some of these intercalates as superionic conductors for advanced batteries, and other applications (to magnetometers and as catalysts) were discussed. Much of this work stems from Yoffe's own group: research at the Cavendish on electrical conductivity of solids now spans the whole spectrum from highly ordered crystals to glasses.

A. R. Ubbelohde (Imperial College, London) demonstrated his enthusiasm for highly controlled pyrolytic carbon, especially the highly oriented, stress-annealed variety: collectively he denoted these materials as "pedigree pyrocarbons". He speculated about the band structure of this class of materials and, by extension, their potential as catalysts.

J. B. Goodenough (newly arrived in Oxford from MIT) spoke with great persuasiveness about the challenges facing the materials expert in the forthcoming burst of research on solar energy. He took his audience on a whirlwind tour of optically designed coated glass cover plates and microgrids for solar heaters, zeolites which show promise as adaptable water absorbers/desorbers for solar air-conditioning

Solid chemical physics

from Robert W. Cahn

A meeting on the Chemical Aspects of Materials Research was held in London on 21–22 March, 1977 under the sponsorship of the Chemistry Committee of the Science Research Council.

THE explicit aim of the meeting was "to stimulate greater activity amongst members of the present chemical community in certain areas of solid state science"—a praiseworthy purpose since in the British chemical family solid-state chemistry has been a poor relation, which some chemists are half-minded to show the door as an imposter. The word "materials" in the title was no doubt intended to stress the fact that this ill-defined branch of chemistry generates its fair share of industrial utility. The title of this report is as accurate a representation as any of what the symposium was actually about; "solid-state chemistry" would have been appropriate had there been more emphasis on reactions. Fuzziness at the borders of disciplines is a symptom of healthy activity: the SRC inevitably sometimes runs into demarcation problems, but makes amends for the occasional administra-

tive *longueur* by its sponsorship of genuinely interdisciplinary meetings such as the one under review.

The meeting consisted of ten hour-long lectures (a few of which are reported below) interspersed by generous discussion time, nowadays a highly untypical format. The value of the symposium was enhanced by the fact that speakers were able to follow their subjects in depth and also follow side-tracks.

B. L. Wilson (Plessey) opened the proceedings with a survey of the 'engineering' of highly alloyed semiconductors with adjustable bandgaps: (Ga, In, Al) (As, P). P. Day (Oxford) concentrated on unusual optical and magnetic phenomena, in particular ionic crystals in which optical absorption can be sharply altered by an applied magnetic field. FeCl₂ is the prototype: separate, ferromagnetically-bonded layers are coupled antiferromagnetically, and the anomalies arise when the layers become magnetically saturated and the salt effectively breaks down into two microphases, nucleation being catalysed by crystal dislocations. Other salts (RbCrCl₄, for example) have, at certain wavelengths, selective peak absorption, the magnitude of which is sharply dependent on magnetisation. In a third category, the tetracyanoplatinates, ionic substitution

(potentially a major application), and the conceptually difficult spectrum of phenomena ranging from straight electrolysis, through electrically assisted photolysis, to straight photolysis of water at electrically connected semiconducting electrodes without benefit of external batteries. (This whole field was initiated by a Japanese paper in *Nature* in 1972.) TiO_2 and SrTiO_3 have been tried, but other semiconductors with smaller bandgaps need to be developed, perhaps with dye sensitisers incorporated. The potential importance of this technology is very great.

In a beautifully lucid lecture G. Allen (Imperial College), basing himself on the Flory-Huggins insights, explained just why useful two-phase polymers can in general only be made by the stratagem of block copolymerisation, which alone permits the correct balance between the tendency to phase separate and the physical impossibility of doing so completely. To a metallurgist used to the interpretation of metallurgical phase diagrams in terms of the configurational entropy of crystalline solid solutions, the rationalisation of polymeric phase diagrams in terms of the configurational entropy of polymer chains was convincing. The laws of mixtures governing the physical properties of such systems were exemplified and the prospects for ungrafted solution-blended two-phase systems outlined. (Physically mixed polymer systems apparently have a Houdini-like proclivity for escaping from their most elaborate entanglements.) The formation of networks from T-shaped monomers was explained. This approach permits the design of tough structural plastics and rubbers, of materials with controlled water permeability and other special-function polymers. In this lecture the rationale of a lifetime's research strategy was made manifest.

The symposium was an unqualified success, and it is to be hoped that the SRC will feel encouraged to continue to sponsor such occasions. □

Green light for the signal hypothesis?

from Pamela Hamlyn

THE work on secreted proteins, particularly those of the liver and pancreas, has demonstrated that these proteins are synthesised on ribosomes bound to endoplasmic reticulum, then transferred through the membrane into the lumen so that their synthesis and secretion form a continuous process. What

is much less certain is the way in which the messenger RNAs which code for secretory proteins are selected for translation by membrane-bound ribosomes. That the selection may be a consequence of a particular nucleotide sequence in these mRNAs, or due to the activity of a separate class of ribosomes, are considerations which have found some experimental support, but the suggestion for which there is most experimental evidence is that it is a characteristic of the protein itself (namely the amino acids found at the amino terminus of a precursor form of the mature protein) which leads to its synthesis by membrane-bound ribosomes. A model for the mechanism by which the ribosome is brought in contact with the membrane by way of the N-terminal amino acids has been suggested by G. Blobel and his colleagues (for example, Blobel & Dobberstein *J. cell Biol.* **67**, 835; 1975).

Some very convincing evidence that it is the protein product, rather than the mRNA or ribosomes, which is responsible for the specificity of attachment of polysomes to membranes, has been produced by Harvey Lodish's group at the Massachusetts Institute of Technology (Wirth *et al. Cell* **10**, 253; 1977). Working with Sindbis virus-infected chicken embryo fibroblasts, they have isolated a 26S viral mRNA which codes for three proteins; one is a core protein which is eventually associated with the 42S RNA viral genome and the other two are glycoproteins required for the lipid bilayer which envelops the mature virus. The proteins are translated sequentially from one initiation site on the mRNA: first the core protein, then the two envelope proteins. This recent report is concerned with the localisation of the polysomes involved in the synthesis of these two classes of protein. It was found that 70% of the 26S RNA is bound to membrane and that newly synthesised core protein is localised on the cytoplasmic side of the endoplasmic reticulum and remains free in the cytoplasm, whereas the envelope proteins remain associated with membrane. Since the same ribosomes translate the same mRNA this is very persuasive evidence that neither the ribosome nor the mRNA determines which proteins are synthesised on membrane. In the model described by Wirth *et al.* it is proposed that at the beginning of translation the 26S RNA is free in the cytoplasm whereas the core protein is synthesised and released. As translation of the envelope protein proceeds, its amino-terminal sequence initiates an interaction with the membrane leading to the ribosome becoming 'membrane-bound'. No amino acid data is available

for the synthesised proteins but it has been observed that the first of the two glycoproteins is produced in a larger form than is found in the lipid envelope.

The light chain of mouse immunoglobulin has been known for some time to be synthesised in a larger form than is eventually secreted. This has been shown to be due to about 20 extra amino acids preceding the amino terminus of the mature protein. Israel Schechter and his coworkers have been working on the sequence of the amino acids in what they call the 'extra piece' in several different light chains (Burstein & Schechter *Proc. natn. Acad. Sci. U.S.A.* **74**, 716; 1977). Two completely sequenced, and other partially sequenced, 'extra pieces' reveal that that although these regions are not particularly homologous in sequence they all contain a very high proportion of hydrophobic amino acids. This fits nicely with the suggestion that this region is responsible for the interaction with endoplasmic reticulum leading to the ribosomes becoming bound to membrane. However, Burstein and Schechter envisage that the hydrophobic region would also allow the protein to associate with other membranes and suggest in particular that it may interact with the cell surface membrane to serve as an antigen-recognising receptor. This hypothesis can be tested experimentally: it will be interesting to see if the 'extra piece' is involved in several different protein-membrane interactions. □

Iranian natural history

from Peter D. Moore

THE past 30 years have seen an enormous expansion in amateur interest in natural history in Europe and North America. This surge has been accompanied and encouraged by a parallel proliferation of field guides for the identification of such organisms as birds, plants and butterflies. Taxonomy apart, these developments have been of great benefit to the serious study of distribution patterns, behaviour and migration. In many other parts of the world, where documentation is at present far less thorough, the galvanisation of the potential mass of amateurs may simply be awaiting the provision of accessible field guides to identification.

Peter D. Moore is a lecturer in the Department of Plant Sciences at Kings College London.

Pamela Hamlyn is at the MRC Laboratory of Molecular Biology, Cambridge.

In Iran, the government Department of the Environment regards such provision as an urgent priority. It began its programme of publishing field guides in 1975 with the production of *The Birds of Iran* (eds Scott, D. A., Hamadani, H. M., & Mirhosseini, A. A.). Many difficulties were faced in the production of that book. The choice of language (the book is written in Persian) the names used for birds in the country (selection from many local names had to be made) and the art work (illustrations from British and French field guides had to be used due to a lack of suitable indigenous artists) all presented problems. The book which resulted is impressive in its scope and the distribution maps are useful even to the non-Persian speaking visitor, if he is prepared to learn and use arabic numerals.

This year has seen the publication by the Iranian Department of the Environment of *A Guide to the Mammals of Iran* (ed. Harrington, F. A.). This time the text is in English and the art work, which has been splendidly executed, was specifically commissioned and was undertaken by R. S. Robinson. All 148 mammals recorded from Iran, including the tiger and the lion which are now probably extinct there, are described and 112 are illustrated. Iran covers a large range of geographical zones in its span between the Gulf and the Caspian and the arrangement of the book is particularly helpful in grouping species into habitat sections rather than using a strictly taxonomic order. In this respect the *Guide* innovates in a manner which may well be emulated in future western publications in this vein. Harrington's broad experience of the Iranian fauna is evident in the text and his work will undoubtedly pave the way for further studies, particularly on detailed geographical distribution in the country. Work is now underway on the next volume in the series which will deal with reptiles.

The difficulties and the needs of the botanist in Iran are rather different. The high central plateau is rich in endemics and the flora is therefore extremely large. A definitive *Flora Iranica* is still in the course of production, being edited and compiled by K. A. Rochinger at Vienna. At present, therefore, the production of popular field guides must await the full description of the Iranian flora, and new species are constantly being described. A higher priority has been the provision of a scientific publication in which the gradually unfolding Persian taxonomic discoveries can be communicated. In the past, most descriptions of new species, local floristic lists and ecological work have been

published in western journals; much taxonomic work has found its way into the *Notes of the Royal Botanical Garden, Edinburgh* for example. Now a new journal has been launched—the *Iranian Journal of Botany*—edited at the Ariamehr Botanical Garden in Tehran. It is evident from the first issue that this will be a most useful source of reference to all who are interested in the flora of the Middle East. Wendelbo provides an annotated check list of Iranian ferns; Eckblad summarised the scant information available concerning the gasteromycetes of Iran; biogeographical implications of newly described species are discussed and a floral list from the important Kavir Protected Region is included. The journal is in English and is lavishly illustrated with colour photographs; it is currently only available directly from the Ariamehr Botanical Gardens.

These efforts of the Iranians to distribute all available information must be highly commended. It must now be seen whether, as in the west, this dissemination results in the encouragement of further work. □

New discontinuity in the Atlantic

from M. Whitfield

ALTHOUGH, from the surface, the oceans may appear as remarkably homogeneous and featureless bodies of water they are in fact made up of an intricate three-dimensional patchwork of individual water masses. These water masses are layered according to their densities which in turn are defined by the salinity (S) and potential or *in situ* temperature (θ) of the component waters. The water masses are therefore most simply identified as clumps of points on a θ/S plot and the relationship between the nutrient (silicate, nitrate, phosphate) and oxygen concentrations and S or θ provide useful additional chemical fingerprints. One of the important tasks of physical and chemical oceanographers is to identify the origins of these bodies of water, to trace their movement through the oceans and to document their eventual decay by mixing with adjacent water masses. Such information is crucial to our understanding of oceanic mixing processes in general and in particular will affect our interpretation of the dispersion of man-made contaminants throughout the oceans.

M. Whitfield is a member of staff at the laboratories of the Marine Biological Association of the UK, Plymouth.

A recent paper by Broecker *et al.* (*Deep-Sea Res.* 23, 1083; 1976) presents the first results of an unusually detailed analysis of water masses throughout the Atlantic and illustrates some of the difficulties involved in unravelling these mixing patterns. They use results from the well-documented GEOSECS cruises which confirm many of the long established features of the Atlantic circulation pattern (Fig. 1). Their data indicate however that the boundary between the North Atlantic Deep Water (NADW, Fig. 1) and the Antarctic Bottom Water (AABW, Fig. 1), as indicated on θ/S plots, is far too sharp to be the result of vertical mixing between these two water bodies. They suggest that yet another water body is sandwiched between these two layers. This water is characterised by a potential temperature of 2°C (hence the name Two Degree Discontinuity Water, TDDW) and a salinity of 34.9‰ (Fig. 1). Water with these characteristics can be generated by mixing water from the North Atlantic, (Northern Component Water, NCW; 8 parts) with colder, less saline water from the Southern Atlantic (Southern Component Water, SCW; 1 part) which has a higher oxygen content and a lower silica content. TDDW can be traced throughout the Central Atlantic (from 35°N to 33°S) at depths from 4,000 m in the north to 3,200 m in the south. The concentrations of nutrients (phosphate, nitrate and silicate) and oxygen of TDDW in the western basins are consistent with the 8:1 mixing ratio. As the TDDW is traced towards the eastern basin the nutrient and oxygen patterns shift in a highly correlated

A hundred years ago

FINNISH papers report that vast masses of smoke are issuing from a mountain adjoining the river Tana, and that the snow in the vicinity has been melted away. The region has hitherto been free from evidences of volcanic activity. The theory has often been advanced that the gradual elevation of the shores of the Gulf of Bothnia is due to volcanic forces, and it is possible that these are finally seeking a vent.

The royal tigress in the Berlin Zoological Gardens, lately brought forth a litter of two, which she utterly refused to take care of. They were accordingly placed amidst the family of a Newfoundland dog, who welcomed the newcomers warmly and bestows upon them all necessary maternal attentions.

From *Nature* 16, 17 May, 54; 1877.

Fig. 1 Basic features of deep water movement in the Atlantic ocean as shown by a GEOSECS track down the centre of the western basin (adapted from Fig. 2 of Broecker *et al. op. cit.*). North Atlantic Deep Water (NADW) originating from the Labrador, Greenland and Norwegian Seas, flows south to split a northerly flow of Antarctic water. The Antarctic Bottom Water (AABW) results from the mixing of Weddell sea water and deep circumpolar water. A warm saline tongue of Mediterranean water (MW) intruding from the east interrupts the northerly flow of the upper layer of Antarctic water. Horizontal shading indicates the approximate extent of basal thermocline waters.

pattern that is consistent with the release of nutrients, originally locked up in biological detritus, by respiration and silica dissolution. It seems likely that upwelling areas off the west coast of Africa provide the main source of this organic debris so that nutrient levels rise and oxygen levels consequently fall on traversing from west to east.

Any hypothesis concerning the origin of TDDW must allow water masses from both ends of the Atlantic to be blended and spread over the whole central region. The rate of spread must be rapid enough to maintain the sharpness of the two degree discontinuity (TDD) against erosion by vertical mixing but not so rapid that the nutrient composition is homogenised throughout the layer. It is a measure of the difficulties inherent in understanding oceanic mixing processes that no convincing or consistent explanation can be given at this time for such a widespread feature.

A steady-state hypothesis proposed by Broecker *et al.* is based on the confinement of deep water movements by the Rio Grande Rise (at approximately 30°S) and suggests that TDDW is generated in the southern half of the Atlantic. This is inconsistent with the fact that the contribution of SCW to TDDW appears to decrease, rather than increase towards the south. It is also difficult to reconcile with observations that a young variety of TDDW (high in ¹⁴C and low in nutrients) is apparently forming just north of the 30°N boundary in the western basin. The alternative is to shed the concept of steady state mixing, which has so far formed the foundation of oceanic mixing models, and to assume that TDDW is a residual feature from an earlier stage in the ocean's history when the intrusion of AABW was much more extensive than it is now. The TDD, as we see it now, represents the cutting edge

of a more recent influx of NADW as it erodes away the remnants of this earlier intrusion from the south. Unfortunately the oxygen concentrations and the ¹⁴C ages of the various water bodies do not support the idea that water in the mixing zone is any older than the over-riding NADW. The mystery over the origin of TDDW is compounded by the fact that inflections in the θ and S against depth profiles are invariably several hundred metres deeper than the TDD in the western basin. This observation, which is inconsistent with the traditional physical picture of vertical mixing invoked in both the steady state and erosional models mentioned above, may provide a vital clue to the origin of this sharply defined and widespread feature.

Molecular genetics at Hirschhorn

by Eleanor Lawrence

The Third EMBO Annual Symposium, entitled Molecular Aspects of Gene Function, was held at Hirschhorn, West Germany, on 26-30 April 1977.

THE molecular biology of gene expression provided an umbrella large enough to shelter topics as diverse as bacterial chemotaxis, how the silkworm lays down its eggshell, and the structure of the cell's microfilament skeleton. But in the mainstream of molecular genetics the most rapid advance is undoubtedly in the dissection of the fine structure of the eukaryotic genome, thanks to the advent of recombinant DNA technology and fast sequencing methods. On the broader front, re-

Eleanor Lawrence is News and Views Editor of Nature.

combinant DNA techniques promise to transform the study of the genetic basis of differentiation and development by bridging the gap between the biochemistry and classical genetic analysis.

At the level of the gene the hunt is now on for the elusive eukaryotic regulatory sequences. The complete sequence of the yeast 5S rRNA gene and its immediate flanking sequences has been determined by W. Gilbert and colleagues (Harvard University). Various interesting features appear in the region immediately preceding the transcribed portion but as yet the sequence alone can give few clues to the RNA polymerase recognition site, and there are no homologies with the well-known palindromic prokaryote promoter sequences. The gene is bounded at both ends by an oligo (dT-dA) tract. An oligo (dA-dT)-rich region has also been found by R. A. Flavell and A. Jeffreys (Amsterdam University) in the 5' region flanking the rabbit α -globin gene. Using globin cDNA plasmids as probes to identify globin gene sequences in rabbit DNA, they have been able to construct a restriction map of the chromosomal gene and its surrounding regions and have subjected these to preliminary analysis.

In the sea urchin histone repeat unit being sequenced by M. Birnstiel and his colleagues (University of Zurich), a partially homologous sequence is found 20 nucleotides upstream of both the histone H1 and H2A mRNA initiation sites, and another homology occurs some 100 nucleotides upstream in both genes. To determine what part if any these sequences play in gene expression Birnstiel intends to use the oocyte transcription/translation system described by John Gurdon (MRC Laboratory of Molecular Biology, Cambridge) (see *Proc. natn. Acad. Sci. U.S.A.* 74, 1502: 1977). In principle, the promoter region could be identified by producing various DNAs containing the gene plus different lengths of flanking sequence and determining which of these are transcribed when injected into the oocyte nucleus. Birnstiel has also made some modifications to the technique which he claims make it easier to use by those inexperienced in oocyte nucleus injection—centrifugation makes the nucleus bulge out the oocyte wall leaving a neat ring of pigment granules as an injection target.

Nucleotide sequences alone have failed to betray the eukaryotic promoters; but novel and exciting techniques of DNA modification (Gilbert) can be used to determine the exact binding position of protein on DNA if the nucleotide sequence is known and may provide a direct handle on the problem. Using the phosphate-specific

reagent ethylnitrosourea, Gilbert has shown that in the *lac* repressor-operator model system the *lac* repressor binds to one side only of the DNA double helix rather than being wrapped around the DNA. The bases involved in RNA polymerase recognition are also being investigated, by examining the effects of RNA polymerase binding to *lac* DNA on the reactivity of the individual bases to modifying reagents.

Another approach to the analysis of *lac* operator-repressor binding was demonstrated by J. H. Miller (University of Geneva). He and his colleagues have used novel genetic techniques (see *J. molec. Biol.* **109**, 275, 303; 1977) to generate repressors with known amino acid changes. Among them is one with almost 10,000 times wild type affinity for operator and which also binds to non-operator DNA such as lambda and SV40. By determining whether this non-specific binding involves any particular sequences they hope to identify those features of the binding sequence which are common to all and thus identify the parts of the operator crucial for repressor recognition. Using the nonsense mutations accumulated during this work, they have also been able to determine the characteristics of one type of mutational 'hotspot'—genetic regions which are much more easily mutated by specific mutagens. They find that the hotspots preferentially mutated by 2-aminopurine and at which mutations also arise spontaneously are always part of a unique sequence which has 5-methylated cytosines in a particular position (the *i* gene has been sequenced by Gilbert and colleagues). This tie-up between methylated bases and mutability leads Miller to speculate on the wider role of methylation *in vivo*.

In connection with recognition sites on mRNA several speakers, especially L. Gold (University of Texas) reminded participants that the three-dimensional structure must be considered and not just the sequence. He illustrated this with reference to a theoretical structure for *lac* repressor mRNA.

Any discussion of eukaryotic gene expression however, has to take into account that in reality eukaryotic DNA is packaged into chromosomes in the form of chromatin. *In vitro* transcription of chromatin provides one way of investigating the possible regulatory role of the associated histone and non-histone proteins. B. O'Malley (University of Houston) reported a set of experiments on transcription of chick oviduct chromatin. Using *E. coli* RNA polymerase, and a plasmid-derived probe of ovalbumin cDNA, he showed that oestrogen-stimulated oviduct chromatin retained transcriptional specificity *in vitro*, and by reconstitution

experiments that this specificity is mediated by non-histone proteins. Although these results are not novel (Paul and Gilmour published similar data several years ago as did other groups) the low level of endogenous sequence, combined with the use of mercurated nucleotide precursors to allow isolation of newly-synthesised RNA, make this work the most convincing presented to date. However, as P. Chambon (Institut de Chimie Biologique, Strasbourg) stated in discussion this is still a controversial area of research and the proponents of chromatin reconstitution do occasionally shift their arguments to meet the latest technical advances. Perhaps the most impressive result O'Malley presented was that he could switch on ovalbumin mRNA transcription by adding the progesterone/receptor complex to isolated 'switched-off' chromatin; this natural hormone switch activated the chromatin some 10 to 50 times over the control. O'Malley is now isolating genome DNA sequences containing the ovalbumin gene by affinity chromatography on cDNA and mRNA cellulose columns, and has already obtained a purification of more than 100,000-fold. Soon he will have sufficiently pure DNA to clone the gene sequences and so be able to study the control regions near the structural gene.

The search for possible gene-specific or sequence-specific DNA-binding proteins which may play a part in regulating the expression of particular genes was illustrated in work reported from W. Gehring's laboratory (Biozentrum, Basle). Two DNA-binding proteins isolated from unfertilised *Drosophila* eggs were shown to bind specifically to two chromosomal fragments from Gehring's bank of cloned DNA fragments representing the complete *Drosophila* genome. One of these hybridises *in situ* only to the nucleolus, strongly suggesting that its corresponding DNA-binding protein is specific for ribosomal DNA sequences; the other hybridises to one band on chromosome 3.

The genetic basis of differentiation and development is now under investigation in a variety of systems. One of the most promising is that described by F. Kafatos (University of Athens) in the silkworm *Bombyx*. Its chorionic proteins which are laid down in strict sequential patterns to form the eggshell, are determined by a system of two or three multigene families whose mechanisms of regulation and expression during differentiation and development are now, with recombinant DNA technology, amenable to full analysis. *Bombyx* also obligingly provides several chorionic mutants for comparative analysis.

After determining the protein electrophoretic pattern at different stages of eggshell formation, Kafatos together with T. Maniatis and colleagues at Harvard University is now constructing cDNA plasmids representing specific chorionic mRNAs, from the heterogeneous mRNA population present during choriogenesis. Some 20 different clones have been identified so far, two of which have been found to represent proteins expressed at the same developmental stage and one at a different stage. By looking at the pulse-labelled nuclear RNA at various stages using the cDNA plasmids as probes, it will be possible to answer the question of whether the protein pattern is controlled by specific transcription or by translation of pre-existing messengers. Chromosomal DNA clones are also being constructed and will be used to determine whether evolutionarily similar chorionic protein genes are linked, to determine whether genes expressed at the same time are linked, and to study the putative regulatory sequences flanking the genes.

One interesting report (arising out of the study of the developmental genetics of the slime moulds) was R. A. Firtel's (University of California, La Jolla) description of translation of a cloned actin gene from *Dictyostelium* in *E. coli* minicells. So far his evidence consists of the appearance of a new protein, which runs in the same position as actin on one-dimensional gel electrophoresis. Confirmation of specific translation awaits the full identification of this new protein.

Now that it has become possible to look directly at the regulatory sequences surrounding the gene a great deal of attention is being focused on the transcriptional control of gene expression. But regulation also occurs at many other levels. Differential stability of mRNAs as well as differential transcription must be invoked to explain the patterns of mRNA abundance and copy complexity found in some developing systems, and R. Williamson (St Mary's Hospital Medical School, London) reviewed evidence that control is also exerted at the stage of mRNA processing from nucleus to cytoplasm. J. Bishop (University of Edinburgh) reported evidence from his laboratory that in different types of mouse cell a substantial proportion of the total mRNA sequences are common to the different cell types at a low level. Margaret Buckingham (Institut Pasteur, Paris) described changes in mRNA copy complexity and abundance in myoblast differentiation and also showed that particular mRNAs are more stable in differentiated myotube compared with myoblast cells, whereas others show no change. □

review article

Super-luminal expansion in extragalactic radio sources

R. D. Blandford*, C. F. McKee† & M. J. Rees‡

Very long baseline (VLB) investigations of compact extragalactic radio sources can often be interpreted in terms of two non-thermal components apparently separating with speeds in excess of the speed of light. Given the conventional physical laws and the cosmological interpretation of large redshifts, the available morphological evidence, while inconclusive, is most compatible with a general class of models in which a signal propagating with a speed close to that of light is scattered by an appropriately shaped screen. Possible observations are discussed which might discriminate between this and alternative explanations.

THE use of very long baseline (VLB) interferometry has made it possible to resolve hitherto inaccessible details of compact extragalactic radio sources, and seems to show that they are made up of two or more components. The original observations have now been repeated at intervals over the past five years, and have revealed that these components are in the process of moving apart. The spectacular implication of this discovery is that, if the radio sources are at the large cosmological distances suggested by their red shifts, the components must be separating at apparent transverse velocities more than twice the speed of light¹⁻³. In this article we review and assess the various theoretical explanations that have been proposed to account for this remarkable phenomenon, our main aim being to emphasise the theoretical and observational uncertainties which must be resolved before these objects can be reliably interpreted.

The projected sizes of the rapidly expanding components are typically only a few parsecs and so they are presumably linked to the primary energy source powering the associated active galactic nucleus—indeed this is one reason why VLB observations are of such great astrophysical interest. However, observations in other parts of the electromagnetic spectrum have sometimes shown even more rapid variations^{4,5}; light travel time arguments imply that the 'prime mover' may be even smaller than the radio source.

We have attempted to provide a loose kinematic classification for the models discussed in this paper as shown in Fig. 1 (although the boundaries between the different categories are rather blurred and the classification is not exhaustive). In 'intrinsic' models, the apparent expansion is directly related to the radio emission process; these models are 'causal' or 'acausal' depending on whether or not the expansion is due to one or more independent events. In 'extrinsic' models, the apparent expansion results from scattering or focussing by the intervening medium along the line of sight.

The radio emission is commonly attributed to an incoherent synchrotron-like process involving relativistic electrons (although the evidence for this is less convincing than for extended radio sources). Many of these sources have had their total

flux monitored^{6,7} for more than ten years and have long been known to be variable. In many cases, the synchrotron hypothesis can lead to a theoretical difficulty, the so-called 'inverse Compton catastrophe'^{8,9}. This can arise if the linear size of the source is limited to the distance light can travel in the time taken for the flux density to halve, thus putting a lower limit on the radiation brightness temperature and energy density and an upper limit on the magnetic energy density. When the dominant contribution to the energy density is in the form of radiation rather than magnetic field, the total energy requirements of the source then become implausibly high. This problem disappears if the sources are expanding with speeds $\sim c$ (refs 9–12). Furthermore, in most sources, the relativistic particle pressure is found to exceed the magnetic pressure⁹. Therefore, unless the relativistic plasma is bound by a much higher density of thermal plasma (and this can probably be excluded¹³ on other grounds), relativistic expansion is to be expected. So these arguments, which are independent of the observed angular structure (and were given before the VLB observations), at least support models involving intrinsic relativistic expansion which as we shall see seem most attractive on other grounds.

Dynamics of relativistic expansion

Our understanding of relativistic gas dynamics is largely derived from solutions of a few idealised problems. We mention some of these here in order to demonstrate that relativistic kinematical effects (discussed below) can be accommodated in a framework that is both dynamically and astrophysically plausible.

Fig. 1 Possible classification of the physical models discussed in the text.

*W. K. Kellogg Radiation Laboratory, California Institute of Technology, Pasadena, California 91125.

†Department of Physics, University of California, Berkeley, California 94720.

‡Institute of Astronomy, Cambridge, UK.

We shall consider first the free expansion of an initially uniform spherical cloud of relativistic gas. If an initially uniform cloud of ultra-relativistic plasma starts expanding from radius r_0 , then the Lorentz factor of the bulk expansion when the sphere attains a radius $r \gg r_0$ would be $\gamma \sim r/r_0$ (refs. 14–16), the material being concentrated mainly in a thin shell of thickness $\sim r_0$. In order to conserve total energy, the internal (thermal) energy per particle, measured in a co-moving frame, must be reduced by a factor $\sim r_0/r$. If the cloud is composed of electrons and protons, then the bulk Lorentz factor will saturate when the energy per particle $\sim m_p c^2$ and the characteristic electron energies will subsequently decay $\propto r^{-2/3}$ if they expand independently from the protons with a specific heat ratio of 4/3. In some models in which the central energy source derives from 'magnetic accretion' on to a Kerr black hole, an electron-positron plasma may be produced¹⁷ and this could attain bulk Lorentz factors comparable with the inferred initial random Lorentz factors of the emitting electrons. Free expansion can occur either impulsively, if the surrounding medium is dynamically unimportant, or continuously in a supersonic wind. If this wind were initially subsonic, then either a nozzle geometry¹⁸ or a relativistically deep potential well¹⁹ would be needed to achieve a steady relativistic trans-sonic change. Variability could be induced in an expanding wind by changing the volume emissivity in a dynamically insignificant fashion. However, if the emission processes are synchrotron and inverse Compton radiation, the observed optically thin power will typically decay very rapidly with radius and so it should be dominated by the model-dependent conditions at small radii²⁰.

Second, we consider relativistic blast waves. If the external medium has a density $\rho > E/r^3 c^2 \gamma^2$, with E the energy of the expansion, then it cannot be ignored. A strong shock front will expand outwards with a Lorentz factor $\sim \sqrt{2\gamma}$. The swept up material will be concentrated within a shell of thickness $\sim r/\gamma^2$ and if the explosion is impulsive with the external medium uniform, $\gamma \sim (E/\rho c^2 r^3)^{1/2}$ (refs. 20–22). When r gets so large that the shock stops being relativistic then there is a smooth transition towards the ordinary Sedov²³ solution. Any realistic dynamics compatible with the VLB data must certainly involve deviations from spherical symmetry. Fortunately these results are easily generalised to non-spherical geometries as long as the expansions are at least mildly relativistic. This is because, to a first approximation, each segment of the expanding shell moves independently. A dynamical advantage of blast wave models is that the shocks can be radiative, so that the mechanical energy associated with the explosion can be transformed to radio emission with a high efficiency. This is in contrast with free or adiabatic expansions and models in which the radio emission is associated with a moving plasmoid.

Finally, we may envisage a fast-moving condensed object. The radio-emitting plasma need not be undergoing any expansion if it is coupled (either electromagnetically or by ram pressure) to a rapidly moving object. One attractive conjecture is that when a binary system comprising two condensed objects (neutron star or black hole) coalesce as a result of the radiation of gravitational waves, tidal effects become important and the individual components are broken up²⁴. One or more components of appreciable size can then be ejected relativistically²⁵. Note that in this case the expansion speeds will be constant, instead of accelerating or decelerating as in the case of free expansion of relativistic gas or relativistic blast waves.

Of course, some aspects of all three possibilities may be involved. For instance, the early phases of an outburst may resemble freely accelerating expansion, followed in the later stages by either gradual deceleration in a uniform medium or sudden retardation when a comparatively dense phase of the surrounding material is encountered.

Kinematics of causal models

When a source changes in a time comparable with its size in units of c , the kinematics of the emitted radiation must be carefully analysed and it is possible for a distant observer to

see apparent super-luminal expansion. For causal models, we imagine that an outburst occurs at a point P at a time $t = 0$, as measured by a distant observer O. A 'signal' such as a blast wave^{20,22} or a burst of low frequency radiation from a newly-formed pulsar^{26–28} then moves radially outwards from P. This signal may either be directly associated with the emission (for example, in the case of a radio-emitting plasmoid)^{10,11} or trigger it (for example, in the case of a low frequency electromagnetic wave that can accelerate electrons but not ions to relativistic energies, so that the electrons are held in place by the inertia of the ions)²⁷. We distinguish four speeds associated with this signal: a group velocity $v_g < c$ which is the material velocity of the signal; a phase velocity v_ϕ which is the space velocity of some directly observed feature such as a radio centroid or the outer edge of a resolved component; v_0 , the apparent velocity observed at O, normal to OP; and the actual physical velocity $v_{em} < c$ of the emitting material or of the frame in which the emissivity is approximately isotropic). In some models all four speeds are different. v_0 and v_ϕ are related by

$$v_0 = \frac{v_\phi \sin \theta}{1 - (v_\phi/c) \cos \theta} \quad (1)$$

or

$$\cos \theta_{\pm} = \frac{v_0^2/c \pm [v_\phi^2 + (v_\phi^2 v_0^2/c^2) - v_0^2]^{\frac{1}{2}}}{v_\phi [1 + (v_0/c)^2]} \quad (2)$$

where θ is the angle between v_ϕ and PO.

In 'ballistic models' of super-luminal expansion, the phase and group velocities are both approximately parallel to OP and usually approximately equal. From equation (1) we then see that $v_0 \leq v_\phi \gamma_\phi$, where equality implies that $\theta = \cot^{-1}(c/v_0)$ large observed speeds v_0 can only occur if v_ϕ , which is generally $< c$, is almost parallel to the line of sight. As an example, consider a spherical model in which $v_g = v_\phi$ is the relativistic radial velocity of a radio emitting shell. If v_g is constant, then the surface observed at a fixed observer time t is an ellipsoid with focus at P and eccentricity v_g/c ^{10,11,20,29,30}. The observed width is the minor axis of the ellipsoid, $2\gamma_g v_g t$, ($\gamma_g = (1 - v_g^2/c^2)^{-1/2}$), and so the observed expansion speed is $v_0 = 2\gamma_g v_g$ which exceeds $2c$ when $v_g > 2^{-1}c$. The observed shape can be straightforwardly calculated when v_g is a function of position. If, for instance, v_g changes only with radius r the locus becomes an ovoid, the blunt end being towards O for a decelerating (and the sharp end for an accelerating) expansion. Provided that $d \ln \gamma_g / d \ln r = -n < \frac{1}{2}$, $v_0 = 2\gamma_g v_g \propto t(-n/(2n+1))$, where v_g is the group velocity of the edge of the observed disk at the retarded time. If the emitting region of the source is enlarging in this fashion then it follows that the actual source dimensions are $\sim \gamma_g$ larger than the projected size (that is, $\sim \gamma_g^2 ct$), assuming approximate spherical symmetry.

Clearly a spherically symmetric model cannot explain double structure. In a straightforward modification, two radio-emitting plasmoids are ejected along anti-parallel directions^{31,32}, the velocity of the nearer making a small angle $\sim \gamma_g^{-1}$ with PO, the super-luminal velocity being mostly attributable to the approaching plasmoid. However, this occurs with a probability $\sim (\cos \theta_+ - \cos \theta_-) \leq 2c^2/v_0^2$, which is typically very small when $v_0 \gg c$.

In 'screen' models, v_ϕ and v_g are approximately perpendicular and the radio emission is triggered by a relativistic signal ($v_g \sim c$) illuminating a pre-existing surface so that $v_\phi \gtrsim c$. Usually v_ϕ is normal to the line of sight so that $v_0 \sim v_\phi$. A possible physical manifestation is the intersection of a relativistic blast wave with a dense plasma (or another blast wave) wherein the kinetic energy can be efficiently radiated away. Of course, with an appropriately designed screen, we have $v_0 \gg c$ (for example, if a relativistic signal illuminates a paraboloidal screen with focus P, axis PO). For a roughly spherical screen of radius R illuminated by a concentric spherical pulse of speed c , a distant observer will see a circle of radius $\sim (2Rct)^{\frac{1}{2}}$

for $t \ll R/c$ that seems to expand super-luminally until the apparent radius $\sim 2^{-1}R$ (refs 33, 34). If the screen is a thin ring (for example, a rotating, gaseous disk surrounding a central gravitating object), then the observer will see an expanding double whose separation is decelerating. (Deceleration is characteristic of screen models and is generally more likely to occur than acceleration.) A rotating searchlight³⁴ forms the basis for a kinematically similar model.

The signal motion need not be rectilinear. One ingenious suggestion³⁵⁻³⁷ is that the emitting electrons are channelled at relativistic speeds along the north and south polar field lines of a magnetic dipole. They would then be visible only when they intersected the line formed by the locus of field lines tangent to OP. If the emitting particles are all generated in a single outburst then an expanding double ($v_0 = 4.4c$ (ref. 35) in the equatorial plane) will be seen aligned with the rotation axis. However, because the synchrotron emissivity falls off so rapidly ($\propto r^{-9}$ if the magnetic moment is preserved), it is difficult to account for the equality of the radio components or to evade prohibitive synchrotron losses at early times in this model.

In most types of simple screen model super-luminal effects can usually be achieved without the observer's having a privileged orientation (in contrast to ballistic models). Apparent velocities $v_0 \gg c$ will, however, only be observed for a fraction $\sim (c/v_0)^2$ of the total emission time (the duty cycle) and the actual size of the screen will typically exceed the observed size by a factor $\sim (v_0/c)$. In 'oriented' screen models, the screen is either localised along the line of sight or a large section of it is almost tangent to one of the retarded ovoids. In this case the observed size can be comparable with the actual size and the duty cycle increased to about unity, but only at the expense of requiring the observer to have a particular orientation with respect to the screen [with probability $\sim (c/v_0)^2$].

One can perform similar calculations for more complex geometries. The results obviously depend sensitively on the shape and orientation of the screen and somewhat on v_s . (Note that in the special cases of the sphere and the ring, the kinematics is independent of v_s .)

In Fig. 2 we display the results of a calculation of the observed shape when a spherical pulse moving with a speed $v_s \sim c$ illuminates an axisymmetric screen tailored to produce an expanding double. In this model, separation speeds $\lesssim 5c$ can be seen with most observer orientations.

The third type of causal explanation, which we term a 'phase' model, arises when v_0 and v_s are mutually parallel, and approximately perpendicular to the line of sight. This configuration occurs when, for instance, a synchrotron source is assumed to trail behind a moving object^{38,39}, expanding transversely to the direction of motion. The point of maximum brightness can move with $v_0 \gg c$ even when $v_s \ll c$; and, in a suitable geometry, an expanding double source can be produced. However, in order that the regions of highest brightness separate with an observed velocity $v_0 \gg c$, it is necessary that the object move along a line lying almost in the plane of the sky, so that $\cos\theta_{\pm} \sim (c/v_0)(1 \pm v_0/v_s)$. This will occur with a probability $\frac{1}{2}(\cos\theta_+ - \cos\theta_-) \sim c/v_0$ (using equation (2)). For orientations outside this range, light travel time effects will reduce and may even reverse the observed velocity. Again this is a serious problem for this type of model as it either requires the sources to be in a super-luminal mode for a small fraction of their life, or that most expansions be non-relativistic. However, it does have an advantage over ballistic and screen models in that the actual source size can be comparable with what is observed ($\sim v_0 t$).

Acausal models

Changes in VLB structure need not, however, be attributed to a single agency. For instance, 'Christmas tree' models^{40,41} have been proposed in which independent sources (lying in a disk, viewed approximately equatorially) light up successively so as to

Fig. 2 Specific example of a 'screen' model. A central 'powerhouse' P, such as an accreting black hole or a compact cluster of pulsars), is presumed to be responsible for the production and maintenance of two anti-parallel beams of relativistic fluid. The walls of these beams are taken to be confocal paraboloids of unit semi latus-rectum. A shock with speed $\sim c$ travels radially outwards from P and radio emission is presumed to occur after this shock hits the channel walls for a duration of $0.5/c$. The observer is inclined to the symmetry axis with the most probable inclination of 60° . The emitting material is pushed radially outward with a mild relativistic speed ($\sim c/3$) so that the radio emission is bright only from those parts of the wall where the radius vector makes an angle $\lesssim 80^\circ$ (corresponding to $\mathcal{D} \sim 1$) to the observer direction. The diagram shows the shapes observed at times $t = 0.5/c, 1/c, 1.5/c$. VLB observations of this outburst with a linear resolution ~ 2 would probably be interpreted in terms of an expanding double source in which the separation speed decelerates from $\sim 5c$ to $\sim 4c$. The flux from the two sources would be comparable, the reduced area in the lower component being somewhat compensated by an increased surface brightness resulting from it being closer to P. Of course, the particular details of this model are *ad hoc*, but it does demonstrate that a super-luminally expanding double source can arise quite naturally in the twin beam geometry. Separation speeds $\sim 10c$ can be achieved if the orientation has a less probable value $\lesssim 30^\circ$, but in this case the observed brightness distribution will probably be less symmetrical and the variation with time more dramatic.

mimic a regular expansion. One objection frequently raised to these models is that only expansions, rather than equal mixtures of expansions and contractions, are generally observed. However, as an example, if there are three stationary radio sources aligned so that they are not quite resolved and the central component flares irregularly with a rise time much shorter than the decay time, whilst the outer components have the time-reversed behaviour, then apparent expansions will usually be observed³⁸. In not all sources is the resolution adequate to exclude this type of model.

Doppler effect

The foregoing discussion has been concerned primarily with the rate of expansion of the projected source dimensions and involved only the source geometry and the effective value of γ_s . The relative surface brightness of different parts of the source depends on various astrophysical effects—particle acceleration, magnetic field strength, energy and isotropy of the hypothetical central outburst and so on, of which our knowledge must be limited. However, one important effect which we can consider is the Doppler shift. Its parameters are given by the factor $\mathcal{D} = [\gamma_{em}(1 - (v_{em}/c) \cos\theta)]^{-1}$ where θ is the angle between the velocity v_{em} of the emitting material and OP. The intensity from a given element of proper

volume is then $\propto \mathcal{D}^{3+\alpha}$ (ref. 42) where α is the spectral index. When the material responsible for the emission shares the group velocity, that is, $\gamma_g \sim \gamma_{em}$, then $\mathcal{D}$ ranges from $\gamma_g(1+v_g/c)$ to $[\gamma_g(1+v_g/c)]^{-1}$ for motion parallel and anti-parallel to OP. On the other hand, if there is no bulk motion and v_g is, for example, the group velocity of a low frequency wave pulse, then there is no Doppler shift. We would argue that the true situation lies between these two extremes which are both difficult to reconcile with the observations.

For ballistic models in which $\gamma_g \sim \gamma_{em} \sim \gamma_0$, those parts of the source which display the largest superlight velocities would all have $\mathcal{D} \sim \gamma_{em}$ and this enhances the probability of observing the effect. Indeed one can even envisage a 'shrapnel' model¹⁰ in which $\sim \gamma_{em}^2$ sources are ejected in random directions but the two with $\theta \lesssim \gamma_{em}^{-1}$ are so strongly highlighted that only an expanding double (with, however, a randomly oriented axis) is seen. On the other hand, one cannot plausibly interpret a super-luminal expanding double as two plasmoids moving in opposite directions unless their proper emissivities decay coincidentally as $\tau^{-(3+\alpha)}$ (ref. 43) where τ is the proper time. (If this were the case then the total flux density should fade $\propto d^{-(3+\alpha)}$ where d is the component separation, a possibility that can already be excluded for 3C273.)

The hypothesis that $\gamma_g \sim \gamma_{em}$ then runs into difficulties because it would give rise to a very non-uniform surface brightness making it particularly difficult to account for equal doubles aligned along a preferred axis. However, if $v_{em} \ll c$ and the Doppler effect does not apply, as can occur in both screen and ballistic models, super-luminal expansion will last only a small fraction $\sim (c/v_0)^2$ of the light travel time across the emitting region. So if one averages over a time interval larger than the light travel time, then only $\sim (c/v_0)^2$ of the flux reaching the observer would be associated with an apparent speed v_0 . Moreover, this applies at every instant if, as seems to be the case for 3C120 (ref. 44), the outbursts seem to overlap. Present observations indicate that the flux from the high speed components is not dominated by a slowly changing background so that some bulk relativistic motion of the emitting material must occur. Note that even a velocity of $v_{em} \sim c/3$ would give brightness varying by a factor $2^{3+\alpha}$ as θ increases from 0 to π . In most sources, the source brightness temperatures directly measured by VLBI are $\lesssim 10^{12}$ K. This implies that only mildly relativistic¹² ($\gamma_{em} \lesssim 2$) bulk Lorentz factors are necessary to evade the self-absorption and inverse Compton constraints in incoherent synchrotron emission models. This is consistent with a model such as that illustrated in Fig. 2 in which the kinematics is dominated by the shape of the screen rather than by bulk motion.

In phase models displaying super-luminal expansion $\theta \sim \pi/2$ and the variation in $\mathcal{D}$ across the source is unlikely to be important even if $v_{em} \sim c$.

Propagation effects in extrinsic models

In extrinsic models, the rapid expansions are attributed to radio propagation effects: a small source switches on, the first radio emission to reach the observer follows a direct route and the apparent expansion results from radiation which is focused or scattered towards the observer after traversing increasingly curved paths with consequent progressively larger time delays. If the radiation is bent through a small angle ϕ while propagating out to a distance r , the apparent size would be $\sim 2\phi r$ and the expansion velocity $v_0 \sim 2c/\phi$. The objection to isotropically scattering stationary screens—that the flux be dominated by back scattered radiation—does not apply in this case as long as $\phi \ll 1$.

In 'local' models, processes operating on scales of tens of parsecs must scatter, reflect, or refract radio wave through angles of a few degrees. However, this can usually only be done at the expense of restricting the size of the central source

of radio waves, assumed to be roughly spherical, to a fraction $\sim c/2v_0$ of the observed size, thus increasing the brightness temperature and exacerbating the 'inverse Compton catastrophe'. By contrast in intrinsic source models the observed source size is typically a lower bound on the total linear dimension.

One specific mechanism that could operate in this way, and is probably at least a complicating factor in other models, is induced Compton scattering⁴⁵. If the brightness temperature of the central source is $T_b > m_e c^2/k \sim 10^{10}$ K, then a surrounding cloud of non-relativistic plasma would have an optical depth to induced scattering of $\tau_{ind} \sim (kT_b/m_e c^2)\phi^4 \tau_{spont}$. (ref. 46) where τ_{spont} is the optical depth to spontaneous Thompson scattering. If $\tau_{ind} \gtrsim 1$ while $\tau_{spont} \ll 1$, only induced scattering will be important and this is restricted to those directions that are already occupied by photons. So in such a model there would have to be a background source of angular size comparable with the maximum observed angular separation the brightness distribution from which would be supplemented by photons contributed by the rapidly fluctuating component. However, as radio brightness temperatures do not much exceed $\sim 10^{12}$ K, induced scattering cannot explain expansion speeds $v_0 \gtrsim 6c$ without invoking a specialised geometry. It also seems difficult to produce an equal double by this mechanism unless the observer happens to be located close to the equatorial plane. Nevertheless, induced scattering does involve a systematic lowering of a photon's frequency, and so a general softening of the radio spectrum is expected as the outburst develops⁴⁵, as is indeed frequently observed. (In extreme conditions, a small increase in radio brightness temperature can even occur).

In an alternative scattering mechanism, radio photons of wavelength λ can be deflected through an angle $\delta\phi \sim \lambda/\lambda_p$ by scattering a longitudinal plasmon of wavelength λ_p (ref. 47). If the turbulent energy density in the plasma surrounding the radio source can be maintained at a level sufficient to scatter each radio photon through $\sim 10^\circ$ then again an apparent expansion will be observed following an impulsive outburst. However, as the scattering cross section per electron $\propto \lambda^2$, the effect is strongly frequency-dependent. When the plasma turbulence is approximately isotropic, the maximum scattering angle $\phi \propto \lambda^2$; and when the plasmons are unidirectional, as they would be if they had a discrete origin separate from the radio photons, then $\phi \propto \lambda^3$. So on these models if most of the radio flux is resolved into an expanding source with speed v_0 then the effect should largely disappear if the frequency is reduced by factors $\sim (c/v_0)^{1/2}$, $\sim (c/v_0)^{1/3}$ respectively, as the observed emission will then be dominated by large angle scatterings from earlier outbursts. Provided that the plasmon phase velocities $\ll c$, the frequency shift associated with these scatterings will be negligible and so the spectral variation in an outburst would have to be intrinsic to the source.

A third possibility is the small angle refraction of radio waves by a surrounding cloud of dense ionised filaments, possibly associated with optical emission lines. (In order to produce an expanding double aligned with the symmetry axis, either the individual filaments must be elongated in the equatorial direction or the distribution of scatterers would have to be extended along the axis.) Scattering angles $\sim 10^\circ$ can be plausibly achieved at cm wavelengths using typical emission line region parameters, but again as the effect is $\propto \lambda^2$ any prominent angular structure should disappear on trebling the wavelength. The available evidence does not support this prediction, which would also include strong deceleration.

A somewhat different local effect might be the obscuration of part of a spherical source by an equatorial disk of free-free absorbing plasma. In this way a closely separate double can be produced. However, in order to see a widely separated equal double, the observer must lie in the equatorial plane.

A possible non-local effect is the operation of a gravitational lens^{48,49}. If a compact mass lies along the line of sight it yields a 'double crescent' image. An angular scale of milli-arc seconds

requires a lens mass $\sim 10^5 M_\odot$. A lens model has the virtue that the components are generally of comparable flux density whenever the magnification is high. However, it does not seem possible to achieve systematic expansion by more than the unmagnified source size, and there would be no reason for expecting compact doubles produced in this manner to display any preferential alignment with the axis of an associated double source. An alternative non-local effect involves intergalactic scintillation associated with fluctuations in the density of plasma in the intergalactic medium or an intervening galaxy⁵⁰. This effect would operate similarly to local scintillation and again would be expected to be strongly frequency dependent.

Observational tests

We have analysed the most important features of several different models designed to explain the prime observational fact of extragalactic VLBI—the prevalence of compact double radio sources expanding super-luminally along a preferred direction. In fact, the observational evidence for this property is derived as much for composite studies of several sources as from detailed investigations of individual nuclei and so must still be treated with considerable caution. Nevertheless, improvements in techniques and processing capacity within the next few years should clarify the picture. On the basis of this feature, we have argued that the most attractive theoretical explanations (that is, those least incompatible with existing observations), involve the illumination of an appropriately shaped screen (for example, the cylindrical walls of two anti-parallel relativistic beams) by a 'signal' moving at the speed of light (for example, a relativistic blast wave or a pulse of low frequency radiation), originating from a more compact central source (which might be a $10^8 M_\odot$ black hole). In these models it seems necessary that the emitting region move outwards with a mildly relativistic speed. The arguments advanced against alternative 'intrinsic' models are mainly probabilistic; and most 'extrinsic' models be ruled out because they predict an apparently unobserved frequency dependence. These arguments too must be treated with scepticism at this stage. We conclude by listing some additional observational tests and outlining the conclusions that it may be possible to draw from them.

(1) Do systematic source motions always correspond to expansions rather than contractions? If so it would form the strongest evidence against naive acausal 'Christmas tree' models. It would be of particular interest to know to what extent successive expansions overlap in time and what fraction of the total compact component flux is associated with moving components, as this would indicate how rapidly the emitting region would have to recover so as to accommodate the next outburst, and how rapidly it would have to expand so that only the front of the source would be observed.

(2) Does the position angle and/or the expansion speed vary during a single outburst? Models involving relativistic bulk motions can produce either accelerating or decelerating expansions. Indeed for those sources where the component separation is observed to expand by a factor ~ 2 , it would be surprising if some change in the observed velocity were not seen. Blast wave models are generally decelerating, whereas free expansions, which are perhaps unlikely in view of the rapid decline with time of their optically thin emission, may accelerate. The expansion rates for screen models are determined mainly by the shape and orientation of the screen, but if the outburst or screen are not axisymmetric, the position angle may change⁵³. One interesting possibility is that the velocity be accurately constant during an outburst. In this case the expansion would probably have to be attributed to one or more coherent objects moving inertially, although in certain conditions blast wave models can exhibit constant velocity phases²¹.

(3) Are the position angle and expansion speed 'remembered' from one outburst to the next? Successive outbursts should

display the same alignment if they represent expansion along a preferred direction (for example, the rotation axis of a central massive object or rotating gas cloud). A reproducible expansion speed would be a strong argument in favour of a screen model, but the absence of such would not necessarily rule it out because the signal velocity v_s could vary between outbursts, which would alter the kinematics.

(4) What are the absolute positions of the components and which ones are moving fastest? Clearly the development of phase stable VLBI would require a considerable technical advance. However, it may be possible to learn which parts of the source are moving if either the nucleus can be resolved into two or more components, one of which is unchanging, or, in the case of triples, if it is assumed that the central component is stationary. Alternatively, for those sources for which there is a sufficiently nearby unresolved radio source (for example, 3C345/NRA0512), it may be possible to obtain some absolute positional information.

(5) How do the components of expanding doubles evolve? If the emission is due to synchrotron radiation, the component size must always be large enough to bring the brightness temperature below the plausible upper limit set by the inverse Compton restriction. It would be important to know how the source size or surface brightness distribution depends on wavelength, and also whether or not a particular component faded out earlier and was a greater fraction of the flux at short as opposed to long wavelengths, as this would be a particular signature of propagation effects. Other models make specific predictions about wavelength dependence³⁹. Some models also make rough predictions about the distribution of surface brightness^{30,51}. For instance, in the twin-beam model^{18,52} illustrated in the figure, we might expect source asymmetry to increase with the apparent velocity. In simple screen models, the faster component would have lower brightness, whereas in models where the Doppler effect is more important, the reverse would be true. In sources showing successive outbursts, higher sensitivity observations would allow an old and fading component to be followed in the presence of a young and bright source. This could considerably improve the interpretation of the kinematics.

(6) What are the polarisation properties of the individual components? If as proposed on some models the emitting electrons are channelled along an effectively rigid magnetic field, then the observed radiation should be strongly polarised normal to the source axis if it is synchrotron radiation³⁶, and parallel if it is curvature radiation³⁷. If the field direction makes a small angle to the line of sight then perhaps a substantial circular polarisation⁵³ could be observed (unless electrons and positrons are created in equal quantities). The induced Compton and plasmon scattering models also predict polarisation directions related to the source geometry.

(7) Can we identify the time when a given outburst was initiated? Brightness temperature limitations generally preclude the possibility of seeing the start of an outburst at radio wavelengths. However, an unusual change in the optical or X-ray output may serve to identify the time origin (for example, in 3C273) which is particularly important in the case of screen models as this would allow a unique inversion of the geometry of the screen if the signal velocity is taken to be c .

(8) Is the position angle of compact double structure aligned with extended radio structure? So far the evidence for this is positive and so this constitutes an argument in favour of the extended sources' being fuelled continuously⁵⁴ by their central components. In these cases it is tempting to suppose that both sources share a common axis defined by the angular momentum of the central regions. However, as yet amongst these sources, only in 3C273 is there evidence for super-luminal expansion and it is very important to discover more examples. This is because, in most extended double radio sources, one can be fairly sure that the axis does not make a small angle with line of sight. So if rapid expansion, with $v_0 \gg c$ are found to be fairly common, it would probably rule out both ballistic and simple

screen models. One important source to study in this context is Cygnus A because in this case there is fairly convincing evidence that the source axis lies in the plane of the sky⁵⁵.

(9) What are the statistical properties of a sample of compact sources? It is already known that $\geq 10\%$ of flat spectrum 3C sources display super-luminal expansion. In some models where ejections occur in a particular direction and Doppler effects are important, the compact components would appear undetectably faint unless our line of sight lies in a privileged range of solid angle. As we have discussed, the probability of this may be related to the observed expansion speed in which case it should be possible to rule out this type of model. (Note, however, that there is a possible selection effect in that sources exhibiting large Doppler shifts will be preferentially included in a catalogue such as 3C.) We doubt that any models of the screen or ejection type could accommodate regular expansions with speeds $v_0 \gg 10c$ in more than a very small fraction of a large sample of sources. If these velocities were observed then they should motivate attempts to develop less unsatisfactory forms of models in alternative categories. On a more ambitious level, if sufficient understanding of the kinematics of a class of sources can be achieved, it may be possible to invert the problem and set limits on plausible values of the Hubble constant (or conceivably q_0).

Finally, we would stress the importance of carrying out systematic multi-frequency source monitoring using a standard (although necessarily somewhat arbitrary) algorithm for converting raw visibility data to source models, and of pursuing programmes that use the same combination of telescopes for successive observations.

Structure of RNA and RNA binding site in tobacco mosaic virus from 4-Å map calculated from X-ray fibre diagrams

Gerald Stubbs*, Stephen Warren* & Kenneth Holmes

Max-Planck-Institut für medizinische Forschung, Abteilung Biophysik Jahnstrasse 29, 6900 Heidelberg, FRG.

The structure of tobacco mosaic virus has been solved to a resolution of 4 Å using fibre diffraction methods. The general fold of the protein is clear, the conformation may be deduced in many places, and the conformation of the RNA and its interaction with the protein can be seen.

Tobacco mosaic virus (TMV) is a rod-like virus, 3,000 Å long and 90 Å in radius, with a central hole of radius 20 Å. The identical protein subunits (molecular weight 17,500) build

a helix of 49 subunits in 3 turns, protecting the RNA. The particles form very well oriented gels^{1,2} which give X-ray fibre diffraction patterns of unsurpassed quality^{2,3}. The first successful calculation of a three-dimensional electron density map was by Barrett *et al.*⁴; however, they limited their analysis to the cylindrically symmetric part of the diffraction pattern, with a resolution of 10–15 Å. They pointed out that with sufficient heavy atom derivatives, the diffraction pattern could in principle be analysed at higher resolution, and Stubbs and Diamond⁵ showed that this could indeed be done. Holmes *et al.*³ applied these methods, to produce a map at 6.7 Å resolution. We report here an extension of the 6.7-Å work: data have been collected to 4 Å resolution and the heavy atom positions have been further refined, producing significant improvements in

*Present address: Rosenstiel Research Center, Brandeis University, Waltham, Massachusetts 02154.

Table 1 Heavy atom derivatives

Ligand	Strain	Site no.	Residue	<i>f</i>	<i>r</i> (Å)	φ (deg)	<i>Z</i> (Å)	<i>R</i> (%)
OsO ₄	Vulgate	1	1	80	92.0	5.5	8.5	12.7

SHIMS, sulphhydryl imidoester²²; MMN, methylmercury nitrate⁸. Units of *f* are arbitrary, and correspond approximately to electrons. *R* is a least-squares *R* factor²³. *r*, φ and *Z* are cylindrical polar coordinates.

the electron density map. The quality of the inner part of the map seems to be what would be expected from a good 4 Å map and this has encouraged us to fit molecular models for the protein and the RNA to the map. We are considerably helped by the fact that most of the RNA binding site is composed of α-helix. We find little ambiguity in the way the atomic models can be fitted to the electron density map. For technical reasons the resolution of the map falls beyond about 60 Å radius so that we have not attempted to build detailed models for this region, although the trace of the polypeptide chain may be seen for the whole of its length.

The application of heavy atom isomorphous replacement to the fibre diagram of TMV has been described^{3,6}. The essential steps are data collection^{3,6}, location of heavy atom sites, calculation of phases and separation of Bessel functions, and Fourier-Bessel inversion⁹. These last two steps are equivalent to reconstructing three-dimensional diffraction data from the observed two-dimensional data. The nature of cylindrically averaged data precludes the use of Patterson methods in locating heavy atoms. Consequently, heavy atom location has been one of the major obstacles to progress in this work. The methods finally used depended on determining the occupancy and radius of a heavy atom from the zero layer line⁷, then finding the other coordinates from the remaining layer lines^{3,8}. Single site derivatives were essential in the early stages, as were double derivatives of these. The heavy atom derivatives used are described in Table 1.

The phase problem for cylindrically averaged data differs from that in crystallography. The intensity of diffraction is⁹⁻¹¹

$$I = \sum_n \mathbf{G}_n \mathbf{G}_n^* \quad (1)$$

G is a vector analogous to the crystallographic *F*. The allowed values of *n* depend upon the helical symmetry of the particle. Three terms of equation (1) should be considered for TMV at 4 Å resolution. Thus the intensity contains six unknown quantities, the real and imaginary parts of three *G_n*, c.f. whereas in crystallography there are only two unknowns. The solution of this multi-dimensional phase problem has been described by Stubbs and Diamond⁸ and Holmes *et al.*³

Electron density map

The map shows clearly recognisable right-handed α helices and resolved sugar and phosphate peaks in the RNA. We have examined 4-Å maps of proteins and a 4-Å map of tRNA produced by Rich and his colleagues, and conclude that by current standards, this is a good protein map, and a particularly good RNA map for this resolution. The exception is the region at radius greater than 65 Å, where the resolution is reduced in the azimuthal direction, falling to 5.5 Å at 80 Å radius (G. S. & S. W., unpublished). However, parallel studies on the crystallised disks of the coat protein¹² will yield detailed information about the outer region, so we have not attempted a detailed fit beyond 60 Å radius.

The RNA stands out as the strongest and clearest feature.

It follows the virus helix at a radius of about 40 Å, as has long been known²⁴, but it is considerably puckered, and in fact lies between 35 and 50 Å. It is a continuous chain, but with a number of interactions with the protein density, and three protruding features which we identify as bases. There are clearly separated peaks along the chain, interpreted as sugar rings and phosphates. The RNA density (without two of the protrusions, which are obscured by the main chain in this view) is shown in Fig. 1a.

The protein chain (158 amino acids) can be traced with confidence for about 70% of its length, from residue 20 to 55, and from 69 to 140. The connecting peptide, the N-terminal chain, and the C-terminal chain are present, but details are less certain, since these all lie at high radius. There are four α helices running approximately radially, which have been described at lower resolution³ and have also been seen at lower resolution in the crystallised coat protein¹². We adopt the descriptive terminology of Champness *et al.*¹² and call these the left and right radial helices (LR and RR), and the left and right slewed helices (LS and RS). Part of the electron density corresponding to the left radial helix is shown in Fig. 1b. It is clearly a right-handed α helix (confirming our choice of hand, made on the basis of the electron microscopy results of Finch¹³) and most of the side chains are marked by density, although not, of course, sufficiently well to recognise them. The same is true of the left and right slewed helices. The right radial helix is not as clear as the other three but is recognisable by its long, straight form, its size and density, and a certain amount of periodicity.

There is also a short stretch of helix at 23 Å radius, the innermost boundary of the protein. We call this the vertical helix (V). This runs parallel with the particle axis, and packs closely with its equivalent helices in adjoining subunits to line the central hole of the virus. Figure 1c shows the density at low radius, where three helices including this one form a bend.

Although the connectivity of these helices was not correctly ascertained at 6.7 Å resolution in the virus³, it was clear at 5 Å in the protein crystals¹² and the chain tracing of Champness *et al.*¹² is confirmed here at 4 Å. In addition, we can trace the chain at low radius, a region which lacks density in the protein map, probably because of disorder¹². The LS helix, beginning near Pro 20, runs inward. It may be slightly shorter than its counterpart in the absence of RNA (see Fig. 1 of Champness *et al.*¹²). It connects to the second helix (RS), which runs from about 50 Å radius outwards, then the chain goes through RR to very low radius, almost meeting the vertical helix, after which the LR helix leads to high radius at about residue 135. The remaining residues are at high radius.

Model building

Protein model building at 4-Å resolution is not normally possible. In the case of TMV, however, many constraints are provided by the abundance of chemical information. Moreover, the map is very clear. The locations of residues Ser 1, Cys 27, Lys 68, and Tyr 139 were fixed by the binding of specific heavy

atom derivatives at those sites^{4,7}. The C terminus is known to be on the outside surface because it is accessible to carboxypeptidase¹⁴. Especially useful were the sequences of over 100 mutants and strains of TMV, indicating which residues are invariant. It was helpful to know the 5 Å structure of the crystalline protein disk¹², which clearly shows the path of the

polypeptide chain connecting the LS and RS helices (residues 31–41), a region which is ambiguous in our map. A most important factor in our ability to build a model was the fact that at radius < 60 Å, TMV is mostly α helical. The atomic model was built with Nicholson push-fit models (1 cm to 1 Å) in a Richards box¹⁵.

Fig. 1 Regions of the electron density map. *a*, The RNA density, with a projection of the model superimposed. One full repeat of the model is shown. Two of the bases lie approximately in the vertical plane and have been omitted for clarity. R indicates a protein side chain. All phosphate groups, sugar rings, and bases, can be fitted into peaks of density. The view is in the direction of increasing *Z*. The 5' end is to the right. The broken line shows the mean radius of the RNA (40 Å). *b*, The left radial helix, with a projection of the main polypeptide chain superimposed. Top and bottom views are shown. *c*, The low-radius density showing the continuous electron density linking the RR helix and the LR helix. $1\frac{1}{2}$ repeats are shown. The vertical stretch has high density and may be fitted to a 10-residue α helix (V) which is terminated by Pro 102 at the N-terminal (RR) end.

Table 2 RNA conformation—angles used for model building

Nucleotide	ϕ (deg)	ψ (deg)	θ (deg)	ξ (deg)	σ (deg)	ω (deg)	χ (deg)
1	70(g^+)	145(t)	220(t)	170(t)	135(C2'-endo)	250(g^-)	110($anti$)
2	275(g^-)	40(g^+)	185(t)	195(t)	135(C2'-endo)	210(t)	170($anti$)
3	290(g^-)	150(t)	135(t)	270(g^-)	135(C2'-endo)	210(t)	105($anti$)

The angle values are unrefined and thus somewhat uncertain. For definitions of angles see Arnott (ref. 16).

The RNA

The RNA has three nucleotides per protein subunit. In the map there is a separate local maximum for every phosphate, every ribose and every base. In order to be certain that only one RNA structure would fit the map, we systematically tried and rejected all but one of the permutations of previously observed conformations of the variable angles. Following the notation of Arnott¹⁶, we used the constraints (1) (ϕ , ψ) $\approx$ (180°, 180°) is not allowed^{17, 18}. (2) $\xi \approx 300^\circ$ implies $\sigma \approx 140^\circ$ (C2'-endo)¹⁹. (3) All bases are *anti*^{16, 18}. (4) All other angles are within or near the previously observed ranges for these angles, as compiled by Arnott¹⁶. (5) Only C2'-endo and C3'-endo conformations were tried as the pucker of the ribose ring; the other possible puckers were judged to differ so slightly from one or the other of these as to be indistinguishable by our methods. (6) Both possible directions of the RNA chain were pursued.

Each conformation tried was set first at a nominal angle and then small variations of the angles were used to improve the fit if possible. Of the approximately 130,000 possible permutations, only about 1,000 had to be tried because many trials were rejected after setting the first few bonds. We were only able to find one conformation which fitted the density. As a check we note that this conformation has the property of being able to repeat as a continuous chain into the next subunit, as required. The geometry of the RNA is given in Table 2. A projection of the RNA, superimposed on its electron density, is shown in Fig. 1a. All three sugars were found to have the C2'-endo conformation. This conformation is found in B-form double helical DNA¹⁶ (ref. 16) and in non-helical regions of tRNA (ref. 18). The three phosphates are at radii 37, 39.5, and 42 Å. The 5' end is at the concave end of the particle. This result has been independently obtained from electron microscopy by Wilson *et al.*²⁰.

The protein

Each helix was first fitted as a polyalanine helix to establish the course of the backbone and to fit β -carbons into bumps of density.

Left slewed helix, residues 21–31—Pro 20 was placed at the bend where the helix starts. The phase of the helix was specified by requiring Cys 27 to be near the MMN site.

Right slewed helix, residues 40–53—Pro 54 was placed at the bend ending this helix. The phase of the helix was chosen to place Phe 48 and Trp 52 into density peaks corresponding to their shapes. This placed Arg 41 near phosphate 1, Glu 50 on the intersubunit boundary, and a hydrophobic face toward Cys 27.

Left radial helix, residues 114–134—The coordinates of residue 139 were known from a specific heavy atom derivative at that site⁴. This site is 22 Å from the corner which ends the LR helix, so the corner residue is likely to be in the range 126–132. A side chain bump of density near that corner, one turn in from the high radius end of the helix, seems to be a ligand for the third UO_2F_6 site. Residues 128–134 are all hydrophobic except for Glu 131 and Arg 134. Since carboxylic acids are known to bind UO_2^{2+} , we placed Glu 131 at that site, which then specified the phase of the LR helix. This positioning required the external face of the helix to be surprisingly hydrophobic. We see below, however, that it functions as a hydrophobic binding site for the RNA bases.

Vertical helix, residues 103–112—It was already known from the radial density distribution of TMV reconstituted protein^{21, 24}

Fig. 2 a, Schematic drawing of the inner part of TMV. The carboxyl cage is formed by the left radial, the right radial, and the vertical helices at a radius of about 30 Å. The view is in the direction of increasing ϕ . B indicates an RNA base. b, The RNA binding site viewed along a radius. The residue numbers of arginines which seem to be forming salt bridges to the phosphates are given. Note how the three bases form a claw which grips the hydrophobic LR helix: LR, left radial helix; RR, right radial helix; P, phosphate.

Fig. 3 Schematic drawing of the carboxyl cage as seen from above.

that the region at 23 Å radius was the densest part of TMV protein. Here we see density which we attribute to a 10-residue α -helix parallel to the cylinder axis. At this radius the 22° wedge-shaped subunit is only 9 Å wide, just the proper spacing for close packing of the vertical helices from adjacent subunits. The important constraint on this helix was that Pro 102 should not be built into it. To connect V with LR (and later to pack residues in density between V and RR), we put Pro 102 at the beginning of the V helix. This choice is supported by the fact that this helix is absent or greatly reduced in size in the U2 strain of TMV²² (and S. Morris, G. S. & S. W., unpublished) which has a proline as residue 107. The phase of the helix was specified by fitting the proper side chains best into density. This fit resulted in the Pb binding site being located between carboxyls Glu 106 and Asp 109 and placed four threonines (103, 104, 107, 111) on the surface exposed to solvent of the central hole (radius 19 Å). Since this assignment of phase has important implications for the existence of a 'carboxyl cage' (see below) experiments with specifically labelled mutants are being undertaken to check this point.

Right radial helix, residues 79–96—The requirement that RR connect with V approximately specified the end residue of RR. The respective consequences of building RR to terminate at each residue in the range 92–101 were noted. The phase which provided the best knobs-into-holes packing with LR put the end of RR at 96. This phase also placed the charged head groups of Arg 90 and Arg 92 into density peaks near phosphates 2 and 3 respectively. At Pro 78, at the high radius end of the RR helix, the chain seems to make a slight bend (becoming steeper in Z) and then to continue out in radius as far as residue 70.

Connecting links—Plausible connecting links were built from LS to RS, from RR to V and from V to LR. For residues 98–101, (ϕ , ψ) pairs were set to be in any of the three major allowed regions of the Ramachandran plot²³ and all 81 permutations were tried. Only one was found which both fit the

density and spanned the required distance. The connection between helices LS and RS (residues 32–40) contains many polar side chains which probably form part of the intersubunit boundary toward the left.

Principal features of the structure

From the model it is evident that the part of the molecule we have built includes four significant regions: the packed helices at medium radius, the RNA binding site, a 'carboxyl cage' and the vertical helix. They are shown in Fig. 2a. We discuss them in order.

The packed helices—As has already been observed¹⁸, the four approximately radial helices pack well together, making angles of 10–20° with each other. Our model has good knobs-into-holes interactions. In the vicinity of Cys 27, the helices form the walls of a hydrophobic pocket: the sulphhydryl is in the centre. The unusual unreactivity of the sulphhydryl has long been known²⁴, and is evidently caused by this environment. This cysteine is conserved in most strains and mutants although its function is not clear. In the cow-pea strain, however, it is replaced by a leucine,²⁵ and since this is of similar size, we might guess that the constraint on residue 27 is the packing of the helices.

The RNA binding site—The RNA lies between subunits in successive turns of the virus helix, so that the binding site is in two halves, between the top of one subunit and the bottom of the next (Fig. 2). One half is the base binding site, located almost entirely on the LR helix. This helix has a large number of hydrophobic aliphatic residues between 117 and 128, which form three faces for the bases. All can accommodate any type of base, since the bases lie flat against hydrophobic side chains. Several residues near the faces, including Thr 89, might form hydrogen bonds with the bases, but the model is not sufficiently accurate to make any definite statement. The other half of the site is mostly on the RR helix, and its principal function is to bind phosphate groups by forming ion pairs, using arginines 90, 92 and 41. The hydrophobic chain of Arg 41 might well be stabilised by interaction with Phe 87, which could occupy a peak of density between the RS helix and the RNA. We note that two other groups on the RR helix, Asn 91 and Asn 98, are in positions where they could form hydrogen bonds with phosphate oxygens, but at this resolution we cannot prove that they do so.

The carboxyl cage—Between the RNA and the vertical helix is the feature illustrated in Fig. 3. Six carboxyl groups are in a pocket which is otherwise lined with hydrophobic residues. The pocket is formed by the LR, RR and V helices of one subunit, and the RR helix of the neighbouring subunit. They are partly neutralised by Arg 112 and Arg 113 (coming from different subunits). It seems likely that lead and uranyl fluoride bind to two or more of these carboxyl groups, and that the carboxyls could form a binding site for other divalent cations. Such binding sites have been observed in other structures^{26–27}, but this is a somewhat unusual example, because of the number of carboxyls involved and because the carboxyls are apparently not fully neutralised by bound metal ions or basic side chains. (Nearby, but apparently not interacting with the carboxyl cage, are Asp 88 and Arg 122, which form an inter-subunit salt bridge.) Caspar²⁸ suggested the presence of pairs of carboxyl groups in TMV with anomalous pK values near 7, and this work was confirmed by Butler, Durham and Klug²⁹. There seems little doubt that the anomalous pK values originate in the carboxyl cage, where carboxyl groups are forced together in a hydrophobic environment, although the situation is apparently even more complex than simple pairs of carboxylic acids. The short vertical helices form a wall, part of the rigid carboxyl cage structure, and protect the RNA from the solution.

TMV assembly

From the above observations, we draw some inferences about the assembly and dissociation of TMV. Caspar²⁸ has suggested

that the carboxyls with anomalous pK values provide a sensitive switch, active in physiological conditions, between the dissociated and intact virus states. Considering the RNA binding region and the carboxyl cage together, we can speculate about the mechanism of this switch. The coat protein has two important states, helix-forming and disk-forming, which are delicately balanced in normal conditions. Switching between the states is controlled by pH , presence or absence of RNA, and possibly by concentration of one or more cations.

The mechanism of the switch seems to involve electrostatic interactions among six carboxyls, five arginines, and when present, three RNA-phosphate groups. The helical state exists either in the intact virus or at low pH . It is characterised by the presence of the interlocking V-helices which force carboxyls together in the 'carboxyl cage', accounting for the abnormal proton binding. In the virus, RNA interactions stabilise this state over a wide range of conditions, even above pH 7 where ionisation of some of the abnormal carboxyl groups can be induced. The disk may be obtained at neutral or high pH in the absence of RNA. Comparing our results with those of Champness *et al.*¹³, the disk is characterised by having no V helix and only half the RR helix. Because of the collapse of the RR helix Arg 90 and 92 are presumably able to neutralise carboxyl groups. This rearrangement (involving about 30 residues) is seen as disordering at small radii in the disk-crystals. Through this mechanism the binding energy of the RNA is partially balanced against the repulsive energy of the 'abnormal carboxyls' which aids uncoating. In the low pH helical-aggregate of the coat problem, where protons establish electroneutrality in the carboxyl cage, the protein can adopt the helix structure, even in the absence of RNA (21, 34, and a 4-Å difference Fourier—E. Mandelkow, S.W. & G.S., in preparation). This suggests the formation of the V-helix may be the factor controlling the disk-helix transition.

Finally, in view of the solid wall formed by the interlocking V-helices, the disordering of the V-helix in the disk, which is an important precursor in the assembling of the virus, is probably necessary to enable the RNA to enter its binding site from the inside hole of the growing virus^{30,31}.

We thank A. Klug and his group in Cambridge, G. Quigley,

A. Rich and A. C. H. Durham for unpublished data, and J. N. Champness and J. E. Ladner for helpful discussions. This work was supported in part by EMBO, the American Cancer Society and Muscular Dystrophy associations.

Note added in proof: Further examination of our model shows that Arg 113 (from the subunit at higher Z) could interact with a phosphate of the RNA. This would take Arg 113 out of the carboxyl cage, and take Arg 41 away from the RNA. Arg 90 would bind to the high-radius phosphate, and Arg 113 to the low-radius phosphate. The structure would be otherwise unaltered. At present we are unable to distinguish between these alternatives.

Transmembrane channel formation in rhodopsin-containing bilayer membranes

M. Montal*, A. Darszon* & H. W. Trissl*

Departamento de Bioquímica, Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional, México 14, D.F.

Rhodopsin has been incorporated into planar lipid bilayer membranes. The effect of light is to increase the bilayer permeability in a pattern consistent with the formation of a transmembrane channel of about 10 Å diameter. A model of visual excitation based on a light-activated and voltage-sensitive channel is presented.

PHOTORECEPTOR cells in both vertebrate and invertebrate species are capable of converting a single absorbed light quantum into a neural signal^{1–3}. The photon is absorbed by rhodopsin, a chromophore-bearing membrane protein⁴. The central problem, therefore, is to determine how a

detected photon can initiate an amplified excitatory response of the receptor cell. It is generally accepted that the light-induced changes in rhodopsin lead to cellular excitation by modulating the ionic conductance of photoreceptor cell plasma membranes^{2,3,5–7}. Such changes could result from a simple mechanism based on rhodopsin functioning as a light-activated ion translocator⁸. A direct way to test this possibility would be to incorporate rhodopsin into a membrane system amenable to the experimental methods required to investigate the postulated transport properties^{9,10}.

Here we describe the properties of planar lipid bilayer membranes with rhodopsin included, and show that light increases the membrane conductance in a pattern consistent with the formation of a transmembrane channel^{10–14}. We propose a heuristic model of visual phototransduction which accommodates the data so far obtained in photoreceptor cells.

*Present address: Department of Physics and Biology, University of California, San Diego, La Jolla, California 92093.

Fig. 1 Time course of the current transition from dark to bleached states. Planar bilayers were formed in a circular aperture of 0.26 mm in diameter as described before²⁹. The Teflon cell consisted of two compartments, each with an area of 3.5 cm². Calomel or Ag-AgCl electrodes were connected to a feedback current amplifier of the type previously described³⁰. The cell and the current amplifier were enclosed inside a light-tight aluminium box. A polarising d.c. voltage, of various amplitudes, was applied across the membrane, the current was displayed on a storage oscilloscope and simultaneously recorded on a strip chart recorder. Bleaching was accomplished with 500 nm light of approximately 10^{16} quanta cm⁻² s⁻¹. All bilayer experiments were done at room temperature. Rod outer segments from dark-adapted bovine retinas (Hormel) were isolated by sucrose flotation and purified in a discontinuous sucrose gradient³¹. Cetyltrimethylammonium bromide (CTAB) was used to extract rhodopsin³². All the steps were performed at 4 °C under dim red light unless otherwise stated. The rhodopsin proteolipid was prepared as follows: detergent (CTAB) solubilised rhodopsin (0.75 mg) was incubated with humid Bio Beads SM-2 (ref. 33) (90 mg) for 5–7 min at 24 °C, and then mixed with a dispersion of partially purified soybean phospholipids³⁴ 10 mg ml⁻¹ in 1.0 ml of 0.1 M KCl, 0.01 M imidazole buffer, pH 7.0. The mixture was sonicated by immersion of the test tube in a water bath sonicator³⁵ for 4 min at 4 °C. Then 0.1 ml of 100 mM CaCl₂ and 1 ml of hexane were added to the suspension. The tube was vigorously mixed for 4 min and the two phases were separated in a clinical centrifuge for 1 min. The hexane phase was removed and a second extraction was performed with 1 ml of ethylether; the suspension was mixed for 3 min and the two phases were separated. The two extractions were performed at 4 °C. The hexane extract exhibits a mean absorbance difference, ΔA_{500} (dark-bleached) of 0.022 ± 0.021 ($n = 20$), whereas the ether extract presents a mean $\Delta A_{500} = 0.183 \pm 0.043$ ($n = 20$). An ether rhodopsin proteolipid with $\Delta A_{500} = 0.16$ was spread over 0.2 M KCl, 1 mM CaCl₂, 0.01 M imidazole pH 7.0. After evaporation of the ether the bilayer was formed. In the figure the membrane current at a voltage of 20 mV is displayed. The arrow represents the point at which the light was switched on.

Planar bilayers which separate two well defined aqueous phases offer the possibility of directly measuring electrical parameters: the time course of light-induced conductance changes together with direct evidence for channel existence can provide insight into the mechanism of rhodopsin action.

Rhodopsin-containing bilayers were made from the rhodopsin proteolipid in organic solvent as described in the legend of Fig. 1. Successful regeneration of rhodopsin treated by this procedure (yield ~70%) showed that it displayed normal spectral characteristics of the native form. The principle of hydrophobic apposition of two monolayers was used for bilayer formation^{9,10,13}. The absolute membrane conductance (G_m) in the dark was in the range $0.2\text{--}2 \times 10^{-9} \Omega^{-1}$; on illumination it increased to a variable extent. Figure 1 is a representative strip-chart recording of the kinetics of conductance transition from the level in the dark ($G_m = 2.1 \times 10^{-10} \Omega^{-1}$) to that in the light. The lag time between illumination and onset of the conductance transition is about 100 s. Estimated half-time of bleaching with the 500 nm light used here is about 3 s. Note that the conductance change proceeds in steps of magnitude of about $4\text{--}8 \times 10^{-10} \Omega^{-1}$ and also in bursts of large magnitude. The difference between the conductance steps and the bursts is more clearly illustrated in the inset, where an oscillographic recording of the same membrane is taken 330 s after illumination: the initial G_m is $32 \times 10^{-10} \Omega^{-1}$, the burst of con-

ductance of $40 \times 10^{-10} \Omega^{-1}$ and the fluctuations in the upper level of G_m are of $5.8 \times 10^{-10} \Omega^{-1}$.

The G_m transition from dark to bleached level may proceed in a 'noisy' way where no identifiable fluctuations can be resolved; this pattern was prevalent in the bilayers prepared from proteolipids with the highest rhodopsin concentration. G_m transition frequently proceeds in steps and bursts concurrent with a drift towards high G_m values. When the dark G_m was initially considerable, or in bilayers formed from a rhodopsin proteolipid which had been purposely bleached, the membrane conductance showed clearly defined fluctuations indistinguishable from those displayed in bleached membranes after the dark to light transition (see below).

This conductance pattern can be recorded in symmetrical media containing either KCl or NaCl as the electrolyte. Ca²⁺ enhances the conductance changes recorded in planar bilayers¹⁰: in the presence of Ca²⁺, the frequency of the conductance fluctuations and the highest levels of conductance reached upon illumination are higher than in its absence.

A distinct latency period between illumination and onset of conductance changes was characteristic in all experiments. Figure 2 illustrates the dependence of the bilayer response time on the rhodopsin concentration present in the proteolipid. Although the total amount of rhodopsin in the proteolipid is known, we have no way of determining the rhodopsin concentration in the bilayer. The latency period varied from 3–200 s and was shorter the higher the rhodopsin content in the proteolipid extract.

In experimental conditions of a steady-state voltage of 20 mV, and a 0.2 M NaCl, 1 mM CaCl₂ solution, three main types of transitions appeared, with amplitudes of about 2, 4 and $6 \times 10^{-10} \Omega^{-1}$ (Fig. 3). The distribution of G_m transitions was equivalent in dark and bleached membranes (Fig. 3). Thus, illumination does not change the fluctuation pattern, it merely increases the absolute conductance and the frequency of fluctuations. A current trace showing the three transitions is shown in Fig. 4. These results indicate the light-induced formation of a channel by rhodopsin.

The individual conductance transitions were ohmic up to 100 mV (Fig. 5). In contrast, the macroscopic G_m was not ohmic but voltage dependent. This is illustrated in Fig. 6: at voltage steps of ≤ 20 mV, G_m displays a steady value with fluctuations of the established magnitude; at voltages greater than about 20 mV the initial G_m relaxes to lower steady-state values. The curve in Fig. 6 shows a region of low voltage sensitivity between 0 and 20 mV. At higher voltages a steep drop of the normalised conductance occurs reaching almost zero. This behaviour establishes the voltage sensitivity of the rhodopsin channel, that is, at high voltage, the channel closes.

Fig. 2 Dependence of the bilayer response time on the rhodopsin content of the proteolipid. Bilayers were prepared from ether proteolipids exhibiting different ΔA_{500} . The time after bleaching required to detect a definite conductance increment is presented in the ordinates. Other experimental conditions as Fig. 1.

As seen from the insets of Fig. 6 the time constants τ_c of closing are in the order of seconds: for example, at a clamping potential of 50 mV the main part of the closing process occurs with a $\tau_c \approx 3$ s. Fast switching the voltage (time constant ~ 30 ms) to zero or inverting the polarity opens the channel. Therefore, the time constant of channel opening is much faster than that for channel closing.

The situation illustrated so far is characteristic of media containing either NaCl or KCl (and 1 mM CaCl_2). But we also made conductance measurements with two other cations— Ca^{2+} and TEA^+ (tetraethylammonium). With both ions in symmetrical 0.2 M solutions, voltage-dependent G_m and G_m fluctuations were seen.

Concentration potential measurements performed in bilayers separating two compartments with different salt

Fig. 3 Histogram of the conductance transitions in dark and bleached states. Only well defined current transitions observed at the steady state voltage of 20 mV in 0.2 M NaCl, 1 mM CaCl_2 , 10 mM imidazole pH 7 of different membranes are collected for the histogram. Two sets of data are presented: transitions in dark (---), and in bleached (—) membranes. Fluctuations of $\leq 0.8 \times 10^{-10} \Omega^{-1}$ and conductance bursts $\geq 8 \times 10^{-10} \Omega^{-1}$ are not included. The ether proteolipids used for the bilayer membranes exhibited ΔA_{500} of $0.17 < \Delta A < 0.26$. Other experimental conditions as for Fig. 1.

activities, showed that G_m is cation selective. Transference numbers for H^+ , K^+ and Ca^{2+} , calculated from the membrane potentials, are 0.85, 0.83 and 0.9 respectively.

The proteolipid in the organic solvent solution contains, in addition to spectrally native rhodopsin, residual detergent, free retinal, and opsin. It is reasonable to ask which of these four components are responsible for the observed effects. Appropriate control experiments were therefore performed: light-induced conductance increases and current fluctuations have been observed with bilayers formed from monolayers of retinal rod disks spread by Trurnit's method, and in this situation, of course, detergent is totally absent^{12,15}. Unfortunately, this system cannot be used

Fig. 4 Membrane current at voltages of +40 and -40 mV from a bleached rhodopsin bilayer. The initial current transient corresponds to the capacitive component. The transition of 2 and $4 \times 10^{-10} \Omega^{-1}$ can be calculated from the positive current record. A transition of $6 \times 10^{-10} \Omega^{-1}$ is recorded in the negative current trace. The G_m fluctuations are not due to steps in bilayer breakdown: they can be recorded even at 10 mV in membranes which are stable up to 3 h. The bilayer was prepared as for Fig. 1.

routinely because of the difficulty in bilayer formation. Alternatively, the recombination of retinal rod disks with phospholipids by sonication allows the extraction of a rhodopsin proteolipid into the solvent with an efficiency comparable with that of the second-ether-extract from CTAB solubilised rhodopsin. It is clear, therefore, that this proteolipid has never been in contact with detergent. Planar bilayers formed from this proteolipid display the same overall behaviour described before in detail: this rules out the participation of the detergent and establishes that rhodopsin is the species responsible of the membrane conductance. The experiments with this proteolipid, which we term 'instant proteolipid', because it speeds up the preparation by obviating the solubilisation step, will be reported in detail elsewhere (in preparation). Another control was done with bilayers formed from proteolipids of opsin (prepared by removal of retinal from bleached rhodopsin¹⁶) which had high conductance ($G_m \sim 10^{-9} \Omega^{-1}$), displayed conductance fluctuations of 2, 4 and $6 \times 10^{-10} \Omega^{-1}$, exhibited a voltage dependent reduction of G_m and, in their overall behaviour, were indistinguishable from those prepared from

Fig. 5 Voltage-dependence of the conductance transitions. The small numbers represent the number of events. Note that the number of transitions decreases as the voltage increases. Experimental conditions as for Fig. 1.

Fig. 6 Voltage dependence of the normalised membrane conductance (G_m at given voltage/ G_m at zero voltage). The figure contains insets of photographs of the current relaxation for voltage steps of 20, 31, 39 and 60 mV, respectively. The lowest line in the photographs represents the baseline at zero current. The initial current peak corresponds to a capacitive transient associated with the onset of the voltage. The vertical scale bars to the right of the photographs represents the current calibration: 50 pA; the horizontal scale bars are the time calibration, 2 s. Two sets of data are presented in the plot: the first set is obtained from four highly conducting membranes ($G_m > 16 \times 10^{-10} \Omega^{-1}$) (●, ○, ×, □); for the second set the four different membranes of low conductance ($G_m < 16 \times 10^{-10} \Omega^{-1}$) (△) were treated as a single membrane.

bleached rhodopsin. As a further control, proteolipids prepared from thermally denatured retinal-free opsin yielded bilayers with low conductance ($G_m < 10^{-10} \Omega^{-1}$); occasional periods of high frequency noise were observed, but these without discernible current step fluctuations. It seems clear, therefore, that the bilayer conductance and its fluctuations are also associated with the presence of opsin. Thus, the variable levels of conductance given by control (that is, dark) rhodopsin-proteolipid bilayers must reflect the presence of variable amounts of bleached rhodopsin (that is, opsin). As noted above, however, whatever the control level of conductance, the effect of light is usually a displacement of the conductance to higher levels.

The planar bilayer experiments have been repeated with proteolipids made from many (>50) different rhodopsin preparations. Light responses of the type shown in Fig. 1 were seen in 30 of the 60 rhodopsin membranes displaying G_m fluctuations. Further technical and analytical refinements should facilitate a more precise characterisation of the bilayer ion-specificity, the kinetics of light-activated responses and light-energy dependence, which could eventually match with the characteristics of photoreceptor membranes².

The light-induced transmembrane channel

It has been shown that light increases the membrane permeability of rhodopsin-containing bilayer membranes. The conductance fluctuations observed in the rhodopsin planar bilayers are of the type induced in lipid bilayers by molecules known to form transmembrane channels^{17,18}. Further, the conductance transitions of the order of $10^{-10} \Omega^{-1}$ indicate a univalent ion flux of 10^8 particles per s for a 100-mV driving force. This calculated flux is higher by four orders of magnitude than the maximal transport rate of an ion-carrier, such as valinomycin, but is the expected value for a channel^{17,18}.

The evidence, taken altogether, establishes that the effect of bleaching rhodopsin in bilayer membranes is to induce the formation of a transmembrane channel. Considering a

channel conductance of $4 \times 10^{-10} \Omega^{-1}$, it is possible to make an order of magnitude estimation of its smallest diameter. Assuming the channel to be a cylindrical pore filled with the bathing electrolyte of bulk conductivity (0.2 M NaCl) and having a length comparable with the membrane thickness of 30 Å, its diameter would be 9 Å (ref. 10). If the channel would be stringently cation selective and using only the Na^+ bulk conductance, its diameter is calculated to be 14 Å. These values seem to be reasonable estimates since the crystal diameter of TEA^+ is about 8 Å (ref. 19) and TEA^+ can pass through the channel. Hydrogen-tritium exchange measurements in rod disk membranes are consistent with the formation of a hydrophilic channel of about 10–15 Å in diameter²⁰, though the data have been recently questioned²¹. Complementary experiments with rhodopsin incorporated into lipid vesicles showed that exposure of the vesicles to light increases the permeability to Na^+ , Cs^+ , Ca^{2+} , glycerol and glucose but not to Cl^- , sucrose and inulin (in preparation). These results indicate that light induces the formation of a wide permeability pathway with a cutoff diameter of about 10 Å. The wavelength dependence of this phenomenon together with a set of control experiments that exclude the involvement of retinal and residual detergent establish that the light response can be accounted for by rhodopsin bleaching¹⁴.

Aggregation can explain the latency of the light response

An immediate obvious difference between the light-induced changes we record *in vitro* and the situation *in vivo* is the relatively long lag period between applications of light and the photoresponse: seconds compared with milliseconds *in vivo*². This difference can be explained by postulating that rhodopsin bleaching changes the permeability by a diffusion limited aggregation process. Such a cooperative process between rhodopsin molecules has been thought to be involved in vertebrate scotopic vision²².

Different models have been considered to explain the experimental observations of the channel and of channel formation in the planar bilayer. A unimolecular channel would be the simplest model. This model suffers from the difficulty of explaining the lag period of the conductance increase after bleaching. The difficulty arises from the assumption that metarhodopsin II, which is produced in milliseconds at room temperature³ (the experimental condition of the planar bilayers), is a conducting species—as seen from the vesicle experiments^{11,14}.

The latency period could be perhaps best explained by a channel formed from rhodopsin units. These aggregating molecules would form after bleaching, and would have to find each other by diffusion in the plane of the membrane. Since the membrane contains only few channels, and thus few aggregating species (assuming a homogenous distribution of rhodopsin), then the observed latency is actually shorter than expected on the basis of unrestricted diffusion. For example, with a diffusion constant of $\sim 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ (ref. 23) for rhodopsin in the bilayer, the molecule travels only 10^{-4} cm in 100 s, that is 1/100 of the actual membrane diameter. To overcome this discrepancy one has to assume that the diffusion occurs in a severely constrained domain. Indeed, examination of the surface layer from which the membranes are formed by phase contrast microscopy, shows patches of the size in question, that is, 10^{-4} cm diameter; they appear white, time stable and probably contain opsin. In contrast, in the disk membrane the protein-protein distance is only tens of Ångströms and so the diffusion-dependent delay is much less than 1 ms, and has no effect on the physiological response time.

Further support for this proposal is that the lag time decreases as the rhodopsin concentration in the proteolipid increases, as seen from Fig. 2.

Once the channel is formed it is fixed and stable. Its

voltage sensitivity cannot be explained by dissociation and subsequent diffusion, since a voltage step to the inverted polarity restores the high conductance state in less than 0.1 s, a time which is considerably shorter than that required for the formation of the channel.

Our favoured model, therefore, is that of a fixed conducting aggregate formed from subunits.

Proposed model of visual excitation

What is the link between the photochemistry of rhodopsin and the bilayer permeability response? The photoisomerisation of the retinal chromophore in rhodopsin triggers transitions in the protein through a sequence of conformational states. The metarhodopsin I to metarhodopsin II transition is the last step in the bleaching sequence which is fast enough to be involved in the transduction process^{2,3}. Since the light-induced permeability in rhodopsin vesicles is elicited at 3 °C, metarhodopsin II may be the first conducting (aggregating) form of rhodopsin.

We have detected capacitative photocurrents in rhodopsin layers from which the bilayers are formed; these arise from charge displacements in rhodopsin as it bleaches²⁴. The photocurrents occur in milliseconds and thus precede the formation of the channel. In analogy to the sodium channel of nerve membranes, where a capacitative—'gating'—current is associated with its opening and closing²⁵, it is tempting to suggest that the measured photocurrents represent the gating current of the rhodopsin channel²⁴.

Irrespective of whether the channel is formed from one or several rhodopsin molecules, it is evident that the amplification gained on allowing the passage of more than 10⁶ ions per s per absorbed photon, is indeed, enormous^{1,2,4,8}.

In vertebrate rods, rhodopsin is located in the intracellular disks and the photoinduced reduction of the 'Na⁺-dark current' occurs in the plasma membrane: a connecting signal between the two membranes is required^{2,3}. Calcium has been postulated as the transmitter²: cytoplasmic Ca²⁺ activity increases during illumination because of a light-induced permeability of the disk membrane to Ca²⁺; Ca²⁺ regulates the 'Na⁺-dark current' by binding reversibly to the plasma membrane sites through which Na⁺ flows into the outer segment. In addition, a Ca²⁺-ATPase has been described in rod outer segments²⁶ and in purified disk membranes²⁷. Based on our findings a model of visual phototransduction can be proposed: in the dark, the channel is closed and the ATPase would pump Ca²⁺ into the disks; on bleaching, the channel

would form and allow Ca²⁺ to diffuse down its concentration gradient. The diffusion of Ca²⁺ would change the disk membrane potential to the value (threshold) at which the channel closes. The channel closure, the photoregeneration of rhodopsin, as well as the activity of the pump, restore the membrane to the conditions existent in the dark. Thus, a light-induced and voltage-sensitive channel constitutes an efficient phototransducer that utilises the well established principles which govern membrane excitability and considers the neural origin of retinal photoreceptors²⁸. There is no evidence at present to extend this scheme to the invertebrate photoreceptors where the situation seems more complex^{2,3}.

We thank G. Feher, C. Gomez-Lojero, D. A. McQuarrie, R. M. E. Parkhouse and M. Philipp for helpful discussions and Jorge Zarco for technical assistance. This work was supported by CONACYT-Mexico (grant to M.M. and fellowship to A.D.) and Deutsche Forschungsgemeinschaft (H.W.T.).

X-ray study of the lithium complex of NAD⁺

W. Saenger, B. S. Reddy, K. Muhlegger* & G. Weimann*

Abteilung Chemie, Max-Planck-Institut fur experimentelle Medizin, Hermann-Rein-Str. 3, D-34 Gottingen, Germany

The Li⁺-NAD⁺ complex exists as a 'dimer' of two molecules arranged head-to-tail with Li⁺ coordinated tetrahedrally to adenine N(7) and three pyrophosphate oxygens. Adenine is stacked intermolecularly on nicotinamide. The conformation of NAD⁺ is 'extended' and similar to that found in holoenzyme complexes. This is in contrast to the 'folded' structure proposed from spectroscopic studies.

*Present address: Boehringer-Mannheim, Biochemica-Werk Tutzing 8132 Tutzing, Germany.

BIOLOGICAL redox reactions are catalysed by enzymes requiring cofactors which receive hydride or electrons from one substrate (oxidation) and donate them to another (reduction). Three main groups of enzymes can be distinguished: those containing the (dissociable) coenzymes NAD⁺ or NADP⁺, those with the (non-dissociable) prosthetic groups FAD or FMN, and the cytochromes. The largest group is that of NAD⁺- or NADP⁺-dependent dehydrogenases of which over 150 have so far been studied^{1–3}.

NAD⁺ was first discovered in 1904 by Harden and Young. It was isolated in 1931 by von Euler and co-workers

Fig. 1 Crystals of the $\text{Li}^+\cdot\text{NAD}^+\cdot 2\text{H}_2\text{O}$ complex.

and its chemical structure was elucidated in 1936 by Warburg and Christian¹. Since then, numerous spectroscopic studies such as fluorescence^{1,2}, circular dichroism³ and nuclear magnetic resonance (proton, C-13 and P-31)⁷⁻¹⁴ have been performed on NAD^+ , NADP^+ and synthetic analogues^{2,15-17} in order to establish the three-dimensional structure. It was found that in aqueous solution, NAD^+ occurs in a 'folded' conformation with the two heterocycles forming an intramolecular stack. Depending on the stack (adenine on nicotinamide or vice versa), right- and left-handed helices result which are assumed to be in a rapid equilibrium with an intermediate 'extended', non-stacked form (see ref. 10 for review).

More direct information about the structure of NAD^+ was obtained from X-ray crystallographic data of its holo-enzyme complexes with lactate dehydrogenase (LDH), soluble malate dehydrogenase (s-MDH) glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and liver alcohol dehydrogenase (LADH) (ref. 1). All four enzymes bind NAD^+ in a related 'extended' conformation and not in the folded form proposed for NAD^+ in solution. These analyses also revealed that NAD^+ can bind with the nicotinamide residue either in the *syn* or *anti* orientation, depending on the enzyme, and thus hydride transfer to the C(4) position can occur from both sides of the pyridine ring (see ref. 2 for classification of A and B dehydrogenases).

Attempts to crystallise NAD^+ date back to 1957 but

until this present investigation no specimens suitable for an X-ray analysis had been reported¹⁸. In this paper we describe our crystallographic studies carried out on the $\text{Li}^+\cdot\text{NAD}^+$ complex.

Experimental procedure

For crystallisation, 1 g lyophilised NAD^+ free acid was dissolved in 0.75 ml water and adjusted to pH 4.0 by slow addition of 1.3 ml 1 N LiOH. Then 2 ml methanol were added and the solution was kept at 20–25 °C for 30 h. The crystallised product (Fig. 1) was filtered off, washed twice with acetone and dried over P_2O_5 in a vacuum. Yield was 0.9 g (90%) $\text{Li}^+\cdot\text{NAD}^+\cdot 2\text{H}_2\text{O}$, and analysis showed NAD^+ (enzymatic with alcohol dehydrogenase, ADH) at 93.5%; water (by Karl Fischer method), 5.5%; lithium (flame photometric), 1.1%; Fp uncorr., 203–204 °C. $\text{Li}^+\cdot\text{NAD}^+\cdot 2\text{H}_2\text{O}$ is free of inhibitors for the LDH-reaction and the test according to Amador¹⁹ gives 10–15% better results than commercially available ' NAD^+ free acid' preparations.

A crystal of dimensions $0.025 \times 0.025 \times 0.2$ mm was isolated from the methanolic solution, sealed with some mother liquor in a capillary and used for all X-ray studies. Space group and cell dimensions are $\text{P2}_12_12_1$ and $a=10.073(3)$ Å, $b=15.839(4)$ Å, $c=17.821(4)$ Å. Intensity data were collected in the $2\theta/\omega$ scan mode by means of an automated STOE four-circle diffractometer using Ni-filtered $\text{CuK}\alpha$ radiation. Owing to the rapid decrease of intensities with increasing glancing angle θ , only a limited data set corresponding to a resolution of 1.09 Å ($\theta_{\text{max}}=45^\circ$) could be measured. Out of the 1365 data, 338 were below the 3σ threshold and considered as unobserved.

The structure was solved by heavy atom and direct methods employing the multisolution tangent formula approach MULTAN²⁰. Although the most consistent phase set derived with the $450E$'s greater than 1.01 had a rather 'high' Karle R -factor of 50.4%, the resulting E -map showed maxima which could be identified as atoms of the pyrophosphate group and of the adenine heterocycle. The rest of the structure was derived using Fourier techniques. Atomic parameters were refined by full matrix least squares cycles with assignment of anisotropic temperature factors to P and O atoms. The Li^+ ion and some hydrogen atoms could be located from a difference Fourier synthesis at the end of the refinement which finally converged at $R=10.0\%$ for the observed data.

NAD^+ structure

As shown in Fig. 2, NAD^+ is composed of adenylic acid and nicotinamide-5'-ribonucleotide fused together in a head-to-head orientation through a pyrophosphate linkage.

Fig. 2 Chemical structure of NAD^+ and atom numbering convention used. The pseudo diad relating the two ribosephosphate moieties is indicated.

From a structural point of view, NAD^+ could be diad symmetrical (neglecting the difference in heterocycles) with the diad passing through the pyrophosphate O(PP) oxygen atom. In the Li^+NAD^+ complex, however, asymmetry is introduced by two Li^+ cations liganded to the same NAD^+ molecule, one attached to adenine N(7) and a free oxygen atom of the P_N phosphate while the second Li^+ occupies the other free oxygen of this phosphate group and one free oxygen of the P_A phosphate (Fig. 3). In this complex the NAD^+ molecule does not exist in the 'folded' conformation with adenine and nicotinamide heterocycles stacked with each other but rather assumes an 'extended' conformation with the planes passing through the heterocycles in an almost perpendicular arrangement.

Fig. 3 Molecular structure of the Li^+NAD^+ complex. Coordination to two Li^+ -ions is marked by filled bonds, parts of the molecule nearer to the observer (adenosine moiety) are indicated by heavier lines. Note that adenine and nicotinamide planes are almost perpendicular to each other.

Conformation of the two nucleotides

For 5'-ribonucleotides the energetically most favoured conformational parameters can be summarised briefly as follows; the sugar is puckered $\text{C}(3')\text{-endo}$ or $\text{C}(2')\text{-endo}$, the heterocycle is in an *anti* position about the glycosyl $\text{C}(1')\text{-N}$ bond, the orientation about the $\text{C}(4')\text{-C}(5')$ bond is *gauche*, *gauche* locating $\text{O}(5')$ 'above' the ribose and, finally, the phosphate group is *trans* to $\text{C}(4')$ (refs 21–23).

In Li^+NAD^+ the ribose bearing the nicotinamide residue is puckered in a $\text{C}(3')\text{-endo}$ envelope form while in the adenosine part the ribose occurs in a $\text{C}(2')\text{-endo}$ twist conformation, probably a consequence of the particular geometrical requirements imposed on the molecule by the coordination of Li^+ to both adenine N(7) and one free oxygen atom of the phosphate group P_N .

In both nucleotides the heterocycles are in an *anti* orientation with torsion angles $\text{O}(1')\text{-C}(1')\text{-N}(9)\text{-C}(8)$ of 52° for adenosine and $\text{O}(1')\text{-C}(1')\text{-N}(1)\text{-C}(6)$ of 15° for nicotinamide riboside. In the latter case, it seems that the positive charge at N(1) modifies the $\text{C}(1')\text{-N}$ bond distance, its value of $1.55 \text{ \AA}$ being significantly longer than the $1.47 \text{ \AA}$ generally observed in pyrimidine nucleosides, but it has no obvious influence on the nucleotide conformation. The orientations about the $\text{C}(4')\text{-C}(5')$ bond and about the $\text{C}(5')\text{-O}(5')$ bond in both nucleotides correspond to those usually considered as preferred, that is, *gauche*, *gauche* and *trans*, respectively.

As in other N(1) substituted nicotinamide moieties, the amide group in NAD^+ is nearly coplanar with the heterocycle, the C-NH_2 bond being *cis*-planar with the $\text{C}(3)\text{-C}(4)$ bond^{24–26}. In the unsubstituted nicotinamide²⁷, however, C-NH_2 is *trans*-oriented to $\text{C}(3)\text{-C}(4)$.

The pyrophosphate linkage

So far, four other crystal structures containing nucleotide pyrophosphate linkages have been reported, ATP, ADP, CDP and CDP-choline^{28–30}. Details of the pyrophosphate group have also been described for the symmetrical di- β -naphthyl-pyrophosphate³¹ and for thiamine-pyrophosphate³² and its hydrochloride³³. In all of these molecules the P-O distances in the P-O-P fragments differ significantly (more than three e.s.d.s) from each other. Although NAD^+ possesses a theoretical twofold symmetry about the pyrophosphate oxygen atom O(PP), the P-O(PP) distances differ greatly with a $\text{P}_\text{A}\text{-O(PP)}$ bond length of $1.56 \text{ \AA}$ and $\text{P}_\text{N}\text{-O(PP)}$ of $1.66 \text{ \AA}$. This is attributable to the asymmetrical Li^+ coordination. As with other pyrophosphates, the P-O-P angle is 133° and this relatively obtuse angle allows eclipsed conformation about the P-O(PP) bonds (torsion angles $\pm 120^\circ$) which are normally avoided. There is thus an appreciable flexibility about the pyrophosphate linkage as demonstrated by the almost evenly filled conformational wheel in Fig. 4. On the other hand, the torsion angle about the 'exo-pyrophosphate' link $\text{O}(5')\text{-P}$ is generally limited to (+) *gauche* with an exceptional -124° for the adenosine part in NAD^+ , probably a result of the steric peculiarities forced by the Li^+ coordination.

Li^+ cation coordination

One of the most interesting aspects of this crystal structure concerns the coordination of the Li^+ cation. The four tetrahedrally arranged ligands N(7), O(N1), O(N2), O(A1) (In this nomenclature, unesterified phosphate oxygen atoms

Fig. 4 Conformational wheel for torsion angles O-P-O-P about the pyrophosphate P-O linkage. Note that essentially all angles do occur except those with *cis*-planar arrangement (near 0°). CDPch, CDPcholine; β -Naph PP, di- β -naphthyl-pyrophosphate; thiamine PP, thiamine pyrophosphate, and thiamine PP-HCl, its hydrochloride derivative.

are indexed 1 and 2 if, looking along the $\text{O}(5')\text{-P}$ bond, they are at 120° and 240° clockwise rotation from the pyrophosphate link P-O(PP) are at distances of $2.13 \text{ \AA}$, $1.86 \text{ \AA}$, $1.92 \text{ \AA}$ and $1.88 \text{ \AA}$ from Li^+ respectively and are provided by two different NAD^+ molecules held together by the Li^+ cation in a head to tail orientation (Fig. 5). One NAD^+ molecule donates the two unesterified pyrophosphate oxygen atoms O(A1) and O(N1) and the other the adenine N(7) and the phosphate oxygen atom O(N2). A similar situation was found in the Na_2ATP complex²⁷ where the adenine N(7) atom is bridged with unesterified oxygen atoms of the γ -phosphate group, the coordination to the more remote γ -phosphate (instead of β -phosphate) probably reflecting the different radii of the cations: $0.68 \text{ \AA}$ for Li^+ against $0.97 \text{ \AA}$ for Na^+ . In this respect one might expect that Mg^{2+} with a radius of $0.66 \text{ \AA}$ would form cation-nucleotide complexes similar to those of Li^+ and not Na^+ or K^+ .

Fig. 5 The $\text{Li}^+ \cdot (\text{NAD}^+)_2$ dimer projected along the intermolecular stack indicated by $\odot$. Stack formation with other, symmetry related molecules in the crystal lattice are marked by arrows. One of the two NAD^+ molecules is drawn in heavier type for clarity.

Adenine and nicotinamide intermolecular stacking

Figure 5 demonstrates that the two NAD^+ molecules linked by one Li^+ cation interact through stack formation ($\sim 3.4 \text{ \AA}$) between the adenine coordinated to Li^+ and the partner nicotinamide. The partner adenine forms a stack with a symmetry related NAD^+ molecule to which it is bonded through another Li^+ bridge and so on. In this stack, the adenine N(6) amino group is close to the pyridine nitrogen atom, and the glycosyl linkages are oriented anti-parallel (Fig. 5), features also observed in the 1-methylnicotinamide-aden-9-yl acetate cocrystallite²⁶ but not in NAD^+ analogues with methylene chains replacing the ribotides^{34,35}. A similar arrangement of heterocycles was also proposed for the intramolecular stack in the 'folded' NAD^+ in aqueous solution^{7,10}.

Interaction between NAD^+ molecules in crystal lattice

As mentioned above, the NAD^+ molecules form Li^+ -coordinated, stacked 'dimers' which complex and stack with symmetry related neighbours, thus generating columns building up the crystal lattice. 'Empty' spaces between these columns are filled with two water molecules per NAD^+ , assisting in the formation of a complicated hydrogen bonding network (to be discussed elsewhere).

In aqueous solution, the 'polymeric' $\text{Li}^+ \cdot \text{NAD}^+$ complex will dissociate into electro-neutral $\text{Li}^+ \cdot \text{NAD}^+$ units with Li^+ coordinated intramolecularly either to N(7) and phosphate oxygen O(N2) or to the free pyrophosphate oxygen atoms O(A1) and O(N1), the remaining two coordination sites of Li^+ being satisfied by water molecules. Li^+ will be distributed between these two positions according to the respective association constants.

Conclusions

It is of particular interest to compare the structure of the $\text{Li}^+ \cdot \text{NAD}^+$ complex with those derived from the numerous spectroscopic investigations carried out in the past two decades and with the conformation of NAD^+ when it forms holoenzyme complexes with dehydrogenases.

Conformation of NAD^+ devoid of Li^+

The $\text{Li}^+ \cdot \text{NAD}^+$ complex represents only one possible low-energy structure of the NAD^+ molecule and with other

(larger) cations unable to coordinate with adenine N(7) and the P_N phosphate oxygen atoms simultaneously, geometries different to those observed here might be obtained. Some features of general importance will remain such as the preferred conformations of the two individual nucleotides but the orientation about the pyrophosphate linkage could change because of the flexibility about the $\text{P}-\text{O}(\text{PP})$ bonds as demonstrated in Fig. 4.

Correlation with results from spectroscopic data

The most conclusive results on the conformation of NAD^+ in aqueous solution have been derived from NMR data. Although the proposal of two helical, 'folded' structures of NAD^+ was criticised in favour of the extended one¹¹, it seems to be corroborated by the numerous data. The helical geometry is even preserved when NAD^+ dimerises at higher concentrations¹⁰. From stereochemical considerations, a 'folded', helical structure for NAD^+ is feasible only if no chelation exists between adenine N(7) and the P_N phosphate group. Owing to the flexibility of the pyrophosphate linkage (Fig. 4), the respective torsion angles can be adjusted to form an intramolecular stack described in Fig. 5 for the $\text{Li}^+ \cdot \text{NAD}^+$ complex; N(6) of adenine is close to N(1) of nicotinamide and the glycosyl linkages are in nearly anti-parallel orientation. It should be noted that such a folding of the NAD^+ molecule can be achieved with the preferred conformations of both nucleotides fully maintained ($\text{C}(2') \text{ or } \text{C}(3')\text{-endo}$; *gauche*, *gauche*; *anti*).

In the light of the structure of the $\text{Li}^+ \cdot \text{NAD}^+$ complex with intermolecular chelation and dimer (stack) formation, however, it seems necessary to look at the interpretation of the spectroscopic data more critically, especially since in most previous work the nature of the counter ion has not been considered.

NAD^+ conformation on binding to enzymes

The crystal structures of enzyme· NAD^+ complexes have been described for LDH, LADH, GAPDH and s-MDH¹. In

Fig. 6 Structures of the NAD^+ molecules in the Li^+ complex (open bonds) and in the ternary complex LDH·pyruvate· NAD^+ ³⁷ (solid bonds; NAD^+ in the holoenzyme complexes has a similar conformation as in the ternary complex). Both molecules are projected on the plane through the nicotinamide heterocycle for easy comparison. Owing primarily to the different conformations about the $\text{C}(4')\text{--}\text{C}(5')$ bonds indicated by arrows, the adenosines are in different orientations relative to nicotinamide although the distances between the heterocycles are comparable. Note that the adenine planes are nearly perpendicular to the nicotinamide planes and that they are related by a 90° rotation: in $\text{Li}^+ \cdot \text{NAD}^+$ the glycosyl $\text{C}(1')\text{--}\text{N}$ bond is nearly vertical to the paper while it is in the paper for the ternary complex.

all of these enzymes, the nucleotide binding sites are geometrically related³⁶ and the bound NAD⁺ molecules display similar conformational features as shown in Fig. 6 for the ternary LDH-NAD⁺-pyruvate complex^{37,38}. It is striking to find that the intramolecular distances between the adenine and nicotinamide heterocycles, 11.5 Å in Li⁺-NAD⁺ and 13 Å in the ternary complex are comparable and that in both NAD⁺ molecules the conformation is such that the planes comprising adenine and nicotinamide are nearly perpendicular to each other. The form of NAD⁺ as found in the Li⁺ complex can therefore be considered as that form recognised by the enzyme before complex formation while the 'folded' conformation with parallel heterocycles about 3.4 Å apart seems to be too different to be directly involved in this process.

The conformations about the C(4')-C(5') bonds for NAD⁺ in the holoenzyme and Li⁺ complexes, however, constitute a significant difference. While for the Li⁺-NAD⁺ complex the preferred *gauche, gauche* conformation is found, it is *trans gauche*, for both nucleotides in the holoenzyme NAD⁺ molecule, corresponding to a high-energy state²³. This conformation has never been observed for any 5'-ribonucleotide except for the modified 6-azauridine-5'-phosphate (ref. 39).

Several factors can force such a drastic conformational change of a molecule, primarily the dehydration of NAD⁺ when diffusing from the aqueous solution to the enzyme surface. Further, the liganded cation will be expelled and replaced by positively charged groups of amino acid side chains lining the NAD⁺ binding site. These groups not only compensate for the positive charge but they can also form hydrogen bonds to phosphate oxygen atoms, to ribose hydroxyl groups and to the nicotinamide residue and, further, the adenine heterocycle fits into a 'hydrophobic' pocket^{1,36}. Together, these small individual forces can obviously induce a significant conformational change of NAD⁺.

Similarities of NADP⁺ and NAD⁺ conformations

NADP⁺ differs from NAD⁺ by an additional phosphate group attached to O(2') of the adenosine part. Because this phosphate is fairly remote from the pyrophosphate linkage, these two groups will not interact directly or by means of a chelated cation, at least as long as the two nucleotides

themselves maintain their preferred conformations. On the other hand, the adenine N(3) atom would be in a suitable position to be liganded by a cation connected with the oxygen atoms of the O(2')-phosphate.

We thank Dr Vic W. Armstrong for critically reading the manuscript and Professor F. Cramer for interest and encouragement. Computations were carried out on the UNIVAC 1108 computer of the Gesellschaft für wissenschaftliche Datenverarbeitung, Göttingen, FRG.

Evidence for a 581-d modulation in the pulse period of 3U0352 + 30

We have shown¹ that 3U0352+30 is an X-ray pulsator with a period of 13.9 min. There is also evidence for a modulation in the X-ray flux at 22 (or possibly 11) h but this phenomenon is less well-defined¹. The X-ray source has been identified with the 6 mag Be star X Per on the basis of position (ref. 2 and references therein) and interstellar absorption column³. Neither modulation has yet been detected in the broad-band optical flux^{4,5}, though there is unconfirmed evidence for a 7-min periodicity in a narrow band centred on 4,686 Å (ref. 6). Hutchings *et al.*⁷ have measured periodic shifts in the profiles of the Balmer and He I spectral lines of X Per with amplitudes of ~ 60 and 10 km s⁻¹ respectively which they interpret as due to orbital motion with a period of 581 d. They suggest that the Balmer

line shifts represent the underlying motion of X Per. This implies a mass for the unseen companion of tens of solar masses and indicates that it might be a black hole⁷. The necessity of reconciling all the X-ray and optical data has caused this interpretation to be questioned^{8,9}. Henrichs and Van den Heuvel⁸ suggest that the 581-d periodicity might reflect the apsidal motion of a neutron star in a 22-h orbit about X Per, while Milgrom⁹ postulates that the true 581-d orbital velocity is given by the He I absorption lines in the spectrum (velocity amplitude ~ 10 km s⁻¹), implying an unseen companion of only ~ 2M_⊙.

Copernicus has observed 3U0352+30 on a total of eight occasions between October 1972 and February 1977 as summarised in Table 1. We have searched five days of data from the observing run in February 1976 for a modulation in the pulsation period due to 22-h orbital motion. For a trial orbital period X the data were multiplied by a masking function F,

such that $F = 1$ for $0.0 < \phi_x < 0.33$ and $F = 0$ for $0.33 < \phi_x < 1.0$, where ϕ_x is the phase of the trial period. The 13.9 min. modulation period is then measured by power spectrum analysis¹. The mask is shifted by $0.16X$ and the process repeated until a complete cycle is covered. In this way an upper limit has been set to $V \sin i$ of 200 km s^{-1} for periods in the range 11–60 h. In Table 2 we give upper limits to the orbital inclination, i , for periods of 11.2, 22.4 and 44.8 h assuming a $20 M_\odot$ primary and a $2 M_\odot$ secondary in a circular orbit.

The mean heliocentric period of the 13.9 min modulation measured from each of the eight Copernicus observing runs is given in Table 1. The technique used to determine these values is as described in ref. 1 except that the uncertainties in the periods have been determined using the formula given by Middleditch and Nelson¹⁰. Numerical simulations on the data show that the confidence level of the uncertainties derived in this way is better than 99%. Table 1 shows that there are significant differences in the periods derived. We have investigated the possibility that these fluctuations are related to the 581-d optical period by fitting a function of the form

$$P = P_0 + P' t + A \sin(2\pi(t - t_0)/P_{\text{orb}})$$

where P_0 is the pulse period on JD 2441317.5 (0 h, 1st January 1972) and P_{orb} and t_0 are the period and epoch of a long term modulation. P_0 , P' , A , t_0 and P_{orb} were allowed to vary so as

to minimise χ^2 . The best fitting value of A is found to be $0.0030 \pm 0.0008 \text{ min}$ ($V \sin i = 65 \pm 17 \text{ km s}^{-1}$), with the corresponding range of P_0 and P' being $13.9332 \pm 0.0002 \text{ min}$ and $-(2.72 \pm 0.07) \times 10^{-3} \text{ min yr}^{-1}$ respectively. The value of t_0 derived differed from that given by Hutchings *et al.* (JD 2442084) by $30 \pm 30 \text{ d}$ while, in the range 400–700 d, the optimum value of P_{orb} was $580 \pm 30 \text{ d}$. For the purposes of assigning confidence intervals^{12,13} to the parameters derived, the uncertainties given in Table 1 were conservatively treated as 1σ gaussian errors. Figure 1 shows the data with the best fit linear trend taken out and folded about a 581-d period. The solid line represents the best fit sine curve whose amplitude, A , is equivalent to a circular orbital velocity of $\sim 60 \text{ km s}^{-1}$.

Our data are thus consistent with a model in which the X-ray pulse period is modulated at the same period, phase and amplitude as the optical modulation found by Hutchings *et al.*¹¹ if an overall downward trend in pulse period is assumed. We consider this latter assumption to be justified since trends of this type are seen in other pulsating sources (for example

Table 2 Upper limits to the orbital inclination i for 3U0352+30

Period (h)	Predicted orbital velocity* (km s^{-1})	Upper limit to i from Copernicus data

ref. 14). We recognise, however, that there are relatively few data, and it remains possible that we are observing (fortuitous) aperiodic fluctuations. More data are required over several 580-d cycles in order to bear out the effect. This will involve a substantial amount of effort because of the timescale of the phenomenon and the sensitivity required. Nevertheless we suggest that such an effort would be worthwhile since it could have important consequences for our understanding of the X Per system. In particular, if our present model of the data is correct we can make the following statements. (1) The secular decrease in period ($P/P \sim 10^{-4} \text{ yr}^{-1}$) suggests that 3U0352+30 is a spinning neutron star¹⁴ and not a white dwarf¹⁵. (2) The agreement in phase between the X-ray and optical modulations uniquely associates 3U0352+30 with X Per. (3) The amplitude of the X-ray modulation is consistent with the Balmer line shifts reported by Hutchings *et al.*¹¹. This is consistent with the premise of Hutchings *et al.* that these lines give the true orbital velocity of the system ($\sim 60 \text{ km s}^{-1}$) and lends support to the idea that this is a triple system with both X Per and 3U0352+30 orbiting an unseen companion with a mass of several tens that of the Sun.

On the orientation of the pulsar space velocity vector relative to the spin axis

A SIGNIFICANT parameter for pulsars for which proper motion data are available is the angle ϕ between the space velocity vector and the spin axis. There are eleven such pulsars (ref. 15 and personal communication from one of the authors). The angle between the spin axis projected on the plane of the sky and the proper motion vector has a value close to 0° for three of them, close to 90° for six and between 0° and 90° for the remaining two. We present here a hypothesis which would explain how the different orientations of the space velocity vector relative to the spin axis arise. We distinguish between three modes of formation of pulsars and show that these correspond to the three different sets of values of the angle.

The supernova explosion of a rotating magnetised star would result in the ejection of double jets along the spin axis¹, and only a part of the stored magnetic energy is sufficient to eject the supernova shell². Since in real stars the field is usually not at all symmetrical between the two poles, one would expect the jet ejection to be an asymmetric process resulting in the neutron star getting a kick along the spin axis. Asymmetric radiation, due to the dipole being off centre, from the resulting pulsar could give it an additional kick along the spin axis³. In other words, pulsars formed from the supernova explosions of single stars should have space velocities along the spin axis; pulsars with $\phi \approx 0^\circ$ (0531+21, 0833-45 and 2016+28) belong to this category.

For a supernova explosion to take place in a close binary system, the primary should have a mass $\geq 15M_\odot$ (ref. 4). The primary evolves quickly, transferring more than two thirds of its mass to the companion before it explodes as a supernova, leaving behind a relativistic star: a neutron star or a black hole. Since the more evolved component is also the lighter (at the time of the explosion), mass ejection will not disrupt the binary⁵.

Two other mechanisms are available in principle for disrupting the binary. (1) The ejected supernova shell could impart a critical impulse to the unexploded companion making it leave the system⁶. It has been shown⁷, however, that this mechanism is not likely to be effective. (2) A highly asymmetric supernova explosion could impart a sufficient kick to the exploding star to push it into a hyperbolic orbit. To disrupt the binary in this manner, the impulse should be imparted in the direction of the orbital motion⁸. It is extremely unlikely that a kick normal to the orbital plane—assuming of course that the spin axis is perpendicular to the orbital plane—would disrupt the system. Highest observed space velocity for single pulsars is around 400 km s^{-1} (ref. 9). Velocities of this order are definitely unable to disrupt a binary system especially if the kick is normal to the orbital plane. So the first supernova explosion leaving behind a relativistic star core is unlikely to disrupt the binary. However, to account for the existence of runaway stars, it is necessary to disrupt some of the binaries at this stage. It should therefore be conceded that some supernova explosions do not leave behind any core¹⁰.

If a neutron star were formed in a massive binary it might tilt the orbital plane and impart a velocity of a few dozens of kilometres per second to the centre of the mass of the binary. It could also make the orbit eccentric but this would eventually become circular due to tidal action forcing the OB type main sequence star into synchronous rotation¹¹. The binary would manifest itself as an X-ray source as long as mass being accreted by the compact star from the OB type star (now a blue supergiant) is large enough to give a measurable X-ray flux¹², but not too large to choke the source¹³. Large mass loss would ensue when the primary evolves beyond the blue supergiant stage and overflows the Roche lobe. The X-ray source would be extinguished and matter start flowing out from the outer Lagrangian point. Enhanced accretion by the neutron star and mass loss from the system would spin up the neutron star¹⁴.

The explosion of the resulting helium star is likely to disrupt the system because it is more massive than the companion neutron star. (If the companion is a black hole, disruption probability would be smaller because then both the members of the system will have comparable masses). The disruption of the orbit would release two neutron stars. The old, reactivated neutron star would move in the orbital plane with its orbital velocity. So it would have a space velocity normal to the spin axis¹⁵. This is how pulsars with $\phi \approx 90^\circ$ (0823+26, 0834+06, 1133+16, 1237+25, 1929+10 and 2021+51) were liberated from binary orbits which were disrupted by the supernova explosions of the companion stars. The exploding star would get a kick along the spin axis¹ and so it will move with a velocity equal to the vector sum of the mutually perpendicular kick velocity and its orbital velocity. Pulsars with $0 < \phi < 90^\circ$ (0329+54 and 0950+08) are thus produced by the supernova explosions in and leading to the disruption of the binary systems.

I thank Dr Rajamohan and Mr T. P. Prabhu for useful discussion and Dr C. Shukre who very kindly updated the data of their paper for my use.

How did barium titanate particulates stick together in the nebula?

TANAKA *et al.*¹ have suggested that there must be barium-rich micro-components in the Allende meteorite. We have confirmed this prediction by discovery of barium-rich particulates (see ref. 2). Figure 1 shows diffuse distribution of Ba-rich particles as well as their clusters; each of apparent particles seems to be composed of finer particulates probably of submicron size. Tanaka and Okumura³ showed that the Ba-rich spots are also high in content of titanium. Figure 2 shows the areal overlapping of the distribution of Ba with that of Ti. Relatively sparse dots for Ti are due to shorter scanning time than for Ba.

The results of electron microprobe studies² show the atomic ratio of Ba to Ti to be almost 1:1. Moreover, based on the data obtained by Tanaka and Okumura³, contents of BaO and TiO₂ in most Ba-Ti-rich portion turn out to be 59 and 34% respectively; the pure chemical formula BaTiO₃ gives the theoretical values 66% BaO and 34% TiO₂. Thus the purity of micro-component as barium titanate is amazingly high. The small difference between actual and theoretical contents may be due either to experimental errors or to the presence of small amounts of other titanates and probably silicates. Palme and Wlotzka⁴ separated a particle (about $20 \mu\text{m}$) rich in refractory siderophile elements Os, W, Re, Ir, Mo, Ru and Pt from the Allende meteorite.

The Ba content of the Allende BaTiO₃ is therefore up to 1.7×10^4 times the corresponding chondritic abundance.

Fig. 1 Distribution of Ba microconcentrates in the matrix of Allende; scale bar indicates 10 μm .

This occurrence of barium titanate can be compared with that of calcium titanate (CaTiO_3), which occurs as perovskite in carbonaceous chondrite^{4,5}. According to Grossman⁶, the condensation temperature of perovskite is 1,647 K at 10^{-3} atm total pressure, implying that this mineral is one of the highest-temperature minerals to be condensed early in the solar nebula. It is important to know whether the condensation temperature of BaTiO_3 is higher or lower than that of CaTiO_3 and what the temperature difference is, but the condensation temperature of BaTiO_3 is not

Fig. 2 Distribution of Ti microconcentrates in the matrix of Allende; scale bar indicates 10 μm .

quantitatively known. It can be assumed from analogy, however, that this compound also has a high condensation temperature.

The Ba abundance⁷ in ordinary chondrites is between 3 and 4 p.p.m. The corresponding abundance⁸ of Sr is around 10–12 p.p.m., so the atomic abundance ratio of Sr to Ba is about 5. We might therefore expect the occurrence of SrTiO_3 in the same sample. Despite the careful X-ray scanning, however, it is significant that we have failed to detect the concentrates of Sr like those of Ba. Even apart from this observation, it is difficult to see how the barium titanate particulates could selectively stick to each other in the nebula. This is of even more interest when the low cosmic abundance of Ba is considered. Thus, is it conceivable that some special factor was operative in this selective sticking of BaTiO_3 particulates? Here we propose that the following unique properties of BaTiO_3 are associated directly with the formation of barium titanate particulates in these conditions.

Barium titanate has five crystalline modifications⁹: cubic, tetragonal, orthorhombic, trigonal, and hexagonal. Except for the hexagonal form which is stable above 1,733 K, other forms are well known for their highly dielectric and ferroelectric properties, while the dielectric constant is a function of temperature¹⁰. In particular, the tetragonal form which is stable between 393 and 278 K is known for being piezoelectric and ferroelectric. The Curie temperature is 393 K.

These physical properties imply that barium titanate fine particulates are liable uniquely to high dielectric polarisation in the presence of electric field and the electric charge is raised on their surfaces. It would be understandable that electrostatic situation like this is very favourable for selective attraction of BaTiO_3 fine particulates into larger particulate or aggregate. If BaTiO_3 particulates had still been floating in the nebula at the Curie temperature (393 K), the selective sticking of BaTiO_3 must have been promoted especially at this temperature (ref. 10). The electric field may have been prevailing due to paleosolar wind¹¹ or to friction of dust grains themselves, although other sources of electric field might be conceivable. It should be noted, however, that even without an electric field, spontaneous polarisation can arise for ferroelectric substance.

This reasoning in terms of electrical characteristics of BaTiO_3 seems to be parallel with the observation by Tanaka and Okumura²; the relatively large cluster of Ba–Ti-rich particles is found in matrix of meteorite rather than in inclusion composed seemingly of higher-temperature minerals. From the presence of magnetite in matrix of Allende, Larimer and Anders¹² estimated the upper limit of 400 K for accretion temperature of matrix. Consideration of the reaction of olivine with water vapour to form hydrous silicates led Anders¹³ to the reaction temperature range of 300–350 K. It should be noted that these numerical values possibly indicating the accretion temperatures for matrix are close to the Curie temperature of BaTiO_3 . (This does not conflict with our understanding that this compound was originally formed at high temperatures.)

As mentioned above, unlike Ba, the concentrates of Sr have not been detected in spite of the chemical similarity between both elements as alkaline earths. One of the plausible explanations of this fact is that the difference in ionic radius between Ca and Sr is smaller than between Ca and Ba, and Sr may therefore be more readily incorporated into calcium minerals. Alternatively, the relevant difference of Sr from Ba may be that the dielectric constant of SrTiO_3 is an order of magnitude lower than that of BaTiO_3 and, in addition, that the Curie temperature of the former is about 70 K, compared with about 400 K for the latter. These two possible explanations may not always be alternatives, but may be cooperative factors.

Discovery of pure ultra-fine particulates of BaTiO_3 opens new aspects in meteoritics. As maintained above, special

attention should be given to the unique electric properties of BaTiO₃. The very wide variation of Ba contents¹ must also be considered—the Allende meteorite does not represent the whole range of products which formed in a closed space box containing every element in proportion to cosmic abundances. Components of strange origin, even if solar, are certainly added in excess to the 'closed-space-box' products.

We thank Dr M. Miyamoto for helpful discussions.

Rates of reaction of HO₂ with HO and O studied by laser magnetic resonance

CONCERN about the depletion of stratospheric ozone by nitrogen oxides released by high flying aircraft¹ and by chlorine species from the decomposition of halocarbons^{2,3} has emphasised the need for laboratory data on the elementary reaction steps involved, particularly those which control the concentration of the hydroxyl radical (HO) in the stratosphere. HO has an important role in both ozone destruction mechanisms, since it combines with NO₂ to form the relatively inert HNO₃ molecule and converts the inactive HCl formed from Cl+CH₄ back into active Cl atoms. In the stratosphere the 'odd hydrogen' species H, HO, and HO₂ are formed by the reactions of O(¹D) with H₂O, H₂ and CH₄ and by the photolysis of H₂O, processes which are comparatively well understood. The odd hydrogen species are interconverted largely by reactions such as

and removed mainly by

The rate coefficients for reactions (1) to (3) are relatively well established^{4–6} but there is no previous experimental determination of k_4 and measurements of k_5 (which have not been based on direct and unequivocal measurements of the concentration of HO₂) have yielded values between 2×10^{-11} and 2×10^{-10} cm³ molecule⁻¹ s⁻¹ (refs 7–9). We report the first direct measurements of the rate coefficients k_4 and k_5 for which we have used the novel technique of laser magnetic resonance.

HO and HO₂ are detected in a fast flow system at total pressures of a few torr and 293 K by using a strong magnetic

field to bring Zeeman components of their ²Π_{3/2}, ⁵/₂ ← ⁵/₂ and 4_{3,2} ← 5_{2,3} rotational transitions into resonance with the 118.6-μm line of a water vapour laser. The molecules are detected within the laser cavity and a thin, rotatable polyethylene Brewster window separates the laser discharge from the gas flow system (Fig. 1). The applied magnetic field is weakly modulated at 35 Hz and signals from a Golay cell, which monitors the laser output through a small hole in one mirror, are passed through a phase sensitive detector system and displayed in derivative form as in EPR. The lines show both Doppler and pressure broadening and, in the case of HO, can exhibit modulation broadening. The method of moments is therefore used to convert the differential traces into integrated absorptions from which the ratio of concentrations of HO₂ and HO can be calculated by using the matrix elements and *g*-factors for the transitions and the rotational partition functions^{10,11} and the dipole moments of the two species (S. D. Peyerimhoff, personal communication, refs 12 and 13 and G. Gillespie quoted in ref. 14).

Absolute sensitivities were established by generating known concentrations of HO using the rapid stoichiometric reaction

The reaction between HO and HO₂ has been investigated by studying three related chemical systems; in each system a stationary state in [HO₂] is established by reactions (7) and (5)

Here measurement of the absolute concentration of HO₂, together with the value of $k_7 = 7.9 \times 10^{-13}$ cm³ molecule⁻¹ s⁻¹ at 293 K (ref. 15) leads to a value for k_5 .

Possibly the simplest system is the reaction of H₂O₂ with HO which has previously been generated in reaction (6) conducted in the presence of a small excess of NO₂ over H atoms. Reaction (6), however, produces equal amounts of NO and HO; with the relatively long residence times used (~70 ms) the decay of HO on the walls ($k_w = 25 \pm 5$ s⁻¹) reduces the concentration of HO below that of NO at the point of H₂O₂ addition. Since reaction (8)

might cause errors in the analysis, other systems which avoid this complication were also investigated. In these, HO and HO₂ are generated by the reaction of H atoms with H₂O₂ and subsequently reactions (7), (5) and (9)

largely determine their concentrations. This reaction was allowed to proceed for about 30 ms and then sufficient NO₂ or O₃ was added to scavenge all the remaining H atoms with concomitant production of HO. Here the ratio of NO to HO is clearly unity if NO₂ is the scavenger and NO is absent when O₃ is used. The concentration of HO₂ present is then essentially governed only by reactions (7) and (5) and can thus be used to deduce k_5 . The central values of k_5 obtained from each type of experiment differed by less than the errors associated with the measurement of flow rates, signal strengths and so on, implying that nitrogen oxides do not interfere significantly in our conditions. The average value found for k_5 was $5.1 \pm 1.6 \times 10^{-11}$ cm³ molecule⁻¹ s⁻¹ at 293 K.

The reaction O+HO₂ was investigated in the reaction system

Fig. 1 Laser magnetic resonance spectrometer for kinetic studies.

O atoms plus H_2O_2 which is described by the following elementary reaction steps

and the relative stationary state concentrations of HO_2 and HO are given by

$$\frac{[\text{HO}_2]}{[\text{HO}]} = \frac{k_3}{2k_4} + \frac{k_7}{k_4} \frac{[\text{H}_2\text{O}_2]}{[\text{O}]}$$

The ratio of the slope to intercept of a plot of this relationship (Fig. 2) is 4.7×10^{-2} which agrees very well with the literature value of the ratio $2k_7/k_3$ (refs 5,15) providing confirmation of the above mechanism. The average value of k_4 obtained from the slopes and intercepts of such plots is $k_4 = 3.53 \pm 1.0 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 293 K.

The values of k_4 and k_5 are close to the expected pre-exponential factors for such reactions and the values should apply at stratospheric temperatures within the present accuracy of our measurements.

Fig. 2 Steady-state radical concentrations in $\text{O} + \text{H}_2\text{O}_2$ reaction.

A further interesting point is that the calculated concentrations of HO radicals in the middle and upper stratosphere are roughly proportional to $(k_4/k_5)^{1/2}$ and this ratio would not be affected by any inaccuracy in the calibration for HO_2 since both rate constants would be affected in a similar way.

Measurements of the rate coefficients of the $\text{H} + \text{HO}_2$ reactions and of the temperature coefficients of these processes are under way and the full details of these measurements will be described elsewhere.

We thank the Manufacturing Chemists Association and the Gassiot Committee of the Royal Society for support and Dr D. K. Russell for discussions.

A new classification of metal catalysts in skeletal reactions of hydrocarbons

GENERAL knowledge about the factors governing the catalytic activity of various metals in different skeletal reactions of hydrocarbons is rather limited. Comparative studies are reported here on the depth of hydrogenolysis and the formation of saturated products of 3-methylpentane (3MP) and methylcyclopentane (MCP) for eleven different

metals. We have found that isomerisation, C_5 ring closure and opening activity of Rh, Pd, Ir and Pt can be correlated with their f.c.c. structure, and their atomic dimensions being in a narrow range. These four metals promote single hydrogenolysis whereas multiple fragmentation is the only reaction observed over Co, Ni, Cu, Ru, Ag, Re, Os. Hydrogenolysis activity and pattern are less characteristic for each group.

Various aspects of metal catalysed skeletal hydrocarbon reactions have been studied recently¹ to give some classification of various catalysts. For example, the depth of hydrogenolysis has been found higher over non-noble (Fe, Co, Ni) than over noble VIIIB group metals²⁻³; Re (and even Os) promote deep hydrogenolysis, too⁶. Cyclopentanic C-C bonds have been reported to be similar to alkanes in their resistance to hydrogenolysis¹, although at least two mechanisms have been proposed for ring hydrogenolysis^{7,8}. Two mechanisms of skeletal isomerisation ('bond shift' and ' C_5 -cyclic') have been found over Pt (ref. 1); Pd, Rh, Ir, Ru have also been reported to isomerise *n*-heptane⁹. Hydrogenolysis has been described as a structure-sensitive reaction¹⁻³, and crystallite size effects may also influence the mechanisms of isomerisation¹.

We intended to compare various metals in conditions at which their catalytic activity is as close to each other as possible. Data in Table 1 are related to selected temperatures corresponding to nearly equal rates of 3MP hydrogenolysis. Hydrogenolysis activity is inversely proportional to the τ values. Crystallite size effects between 'powders' and 'blacks' are indicated by the fact that higher τ values are required in the former case to ensure identical activity per unit of surface. The depth of hydrogenolysis can be characterised by a fragmentation factor ζ . This is defined as the number of fragment molecules per molecule of hydrocarbon hydrogenolysed. This value is apparently independent of the structure of the initial hydrocarbon, the origin of the catalyst (that is, of its crystallite size) and the actual τ values at a given conversion level and given hydrogen pressure. C_6 product formation is characterised by the ratio of alkane isomers.

The metals studied seem to fall into two different groups. Group A contains four noble VIIIB metals—Rh, Pd, Ir, Pt—with ζ values near to two which means that single rupture of the molecule predominates. They promote isomerisation and C_5 -cyclisation of 3MP and produce very

high amounts of C_6 alkanes from MCP without altering the fragmentation yields and ζ values as compared with 3MP. On the other hand, the product spectrum over Group B metals including Co, Ni, Ru, Re, Os (and also Cu and Ag where τ was not reached) consists of fragments only except for Ru which produces traces of C_6 isomers. The ζ values between 3 and 6 indicate the multiple breakdown of the molecules. C_6 -alkanes represent a minor fraction of the product spectrum from MCP, their formation being apparently a part of the general scheme of molecular breakdown.

2MP/nH ratios show that alkane production from 3MP and MCP should be related processes; these ' C_5 -cyclic reactions' (including C_5 ring closure, opening and their combination: C_5 -cyclic isomerisation) are confined to group A metals. The higher rate, lower energy activation and different selectivity of ring opening indicates that it represents a particular type of C-C bond rupture distinct from either single or multiple alkane hydrogenolysis. Obviously, the difference can be attributed rather to the nature of the metal than to the structure of MCP¹⁰.

The pathways of cyclohexane dehydrogenation (through flatly or edgewise chemisorbed rings) have been correlated with the catalyst surface geometry, group A metals being the flatly adsorbing ones¹¹. These metals (and only they) have f.c.c. lattice with interatomic distances between 2.69 and 2.77 Å (ref. 12). With such a geometry, the spacing between interatomic holes on the closest packed (111) plane is appropriate (Rh: 1.55 Å Pt: 1.61 Å) for accommodating neighbouring carbon atoms of a hydrocarbon (C-C bonds between 1.522 and 1.546 Å (ref. 13)) over these sites. Such surface intermediates are suggested for single hydrogenolysis without disputing ideas about their nature or dissociated character¹⁻³. From Pt to Rh the ζ value remains almost constant (Table 1); with other surface geometry, the sharply increasing ζ values indicate that multiple hydrogenolysis should involve other surface species. We tentatively suggest that these are bonded to the top of metal atoms.

The concept of flatly chemisorbed C_5 -cyclic intermediate (suggested for C_5 -cyclisation over Pt (ref. 14)), can be extended for every C_5 -cyclic reaction over each group A metal. One active site may serve as a binding site (interacting preferably with the tertiary carbon atom), the other acting as a catalytic site for ring opening and/or closure.

Such species also require definite surface geometry: with spacings that are too large (e.g. Ag) the chain ends cannot come together; with decreasing atomic diameter, the relative importance of hydrogenolysis as against isomerisation increases (cf. Table I), indicating that the attraction of next nearest neighbour sites from smaller and smaller distances gradually suppress C₅-cyclic reactions and promotes hydrogenolysis.

This concept is in agreement with the electronic inequality of tetrahedral (e_g) and octahedral (t_{2g}) sites¹³; it may also explain both the necessity of hydrogen for C₅-cyclic reactions¹⁴ and the selectivity (Fig. 1).

There are two possible explanations for c.p.h. Re and Os with proper atomic dimensions belonging to group B, in spite of the similarity of f.c.c. (111) and c.p.h. (0001) faces. The probability of occurrence of analogous crystallographic planes may not be equal¹²—higher hydrogenolysing activity on c.p.h. Ru and Os was explained this way¹⁶. Or the discrepancy may underline the role of sites where the geometry is favourable on f.c.c. metals only (e.g. steps or B₅ sites¹⁷) (Fig. 1).

Fig. 1 Possible geometry of chemisorption over platinum (111) plane. The dimension of metal (larger circles) and carbon (smaller shaded circles) atoms is to scale. *a*, 1, 2, 3-chemisorption with participation of both e_g and t_{2g} sites leading to hydrogenolysis (1, 2- or 1,3-sorption is also possible); *b*, 3MP chemisorption over two neighbouring t_{2g} site, with hydrogen atoms blocking more active e_g sites; *c*, one of the possible accommodations of MCP along a step [exposing (311) sites^{18,19}] ring opening over the B₅ site would give 2MP, over the neighbouring t_{2g} site 3MP; *n*-hexane formation is hindered.

We do not want to suggest that surface geometry is the only influence: the crystal parameters are outward manifestations of the collective interactions between individual atoms, but it should be pointed out that surface electronic inhomogeneity may create active sites the geometry of which may also be important in catalysis.

Surface wind and sea waves in a hurricane field

THE hazards associated with a hurricane are extremely strong wind, violent seas and heavy rain. Over the seas, heavy rain does not pose as much problem as the other two. It is very rare to get detailed information of surface winds and waves in the hurricane field over the seas. The only set of documented data regarding surface wind and heights of waves is by Arakawa and Suda¹ describing the experience of main squadron of the Imperial Japanese Fleet as it inadvertently passed through the typhoon of September 1935. These simultaneous observations of weather and sea conditions are some of the best data on record. The hurricane reconnaissance over the Atlantic and Pacific could give the structure of winds in the hurricane field at 1000 ft or more above sea level, but no detailed observations about surface winds and waves are available.

Fig. 1 Cyclone tracking by radar fixes of storm in Arabian Sea 30 May-3 June 1976, showing position of drilling rigs.

During the period 31 May-3 June, 1976, a cyclonic storm passed over Arabian Sea. On 2 June it reached hurricane stage and passed through Bombay High Area where off-shore oil explorations are being conducted by the Indian Government. Fig. 1 gives the track of the storm with the positions of three jacked-up rigs: Haakon Magnus, Shenan Doah and Sagar Samrat. The storm centres referred to here are derived from the radar observations at the Area Cyclone Warning Centre, Bombay. It is a 10-cm radar with an effective range of 400 km. The rigs continuously recorded observations of wind and wave. The wind observations were made by standard wind instruments installed at the rigs and the wave measurements were taken with reference to the markings on the legs. These wave

Fig. 2 Wind field over storm area, showing wind speed in knots. The arrow shows the direction in which the storm is moving.

observations are therefore taken to be more accurate than could be done on board a ship.

A composite wind speed chart was plotted throughout the day on 2 June. There was little variation with time: and the hurricane strength was maintained. The isotachs were drawn on this composite chart to determine the distribution of wind speed over different sides of the storm. This is shown in Fig. 2. It is seen that the strongest winds are found in the right rear quadrant and is very similar to the one found by Hughes² from aircraft reconnaissance of tropical storms over Pacific Ocean. Our observations differ from those of Arakawa who found the core of strong winds both in front and rear quadrants on the right side.

Fig. 3 Composite chart showing wave heights and directions. C indicates confused direction.

The composite chart for wind direction was also plotted (figure not presented). It was seen that the centre of the storm as determined by radar did not agree exactly with the convergence centre of wind pattern. The difference was found to be 20 km, the wind centre being to the right of radar centre.

The composite chart for wave heights and directions is shown in Fig. 3. The pattern is similar to one found by Arakawa for the sea in a typhoon, except that we found the highest waves both in the front and rear quadrants of the right side, whereas they found them in the right rear quadrant only. Wave directions generally agree with the theoretical model³. The sea was confused from the centre to the right rear quadrant.

The periods of waves varied between 6 and 12 s. The wave energy is given by $E = 41 H^2 T^2$ ft lb per foot of wave crest per wave length⁴. The maximum energies of waves encountered by the rigs were calculated (see Table 1).

Table 1 Maximum energies of waves encountered by rigs

Rig	Wave energy, E (10^6 J)
Sagar Samrat	1.72
Haakon Magnus	5.01
Shenan Doah	1.18

Energy values are given per metre of wave crests per wave length.

Assuming that the energy of wave is due to transfer of kinetic energy from air-water-surface interaction *in situ*, $E_{\max}$ is expected near the centre of the storm. This is confirmed by the value we get for Haakon Magnus.

We thank the Chairman, Oil and Natural Gas Commission, Government of India, for allowing us to use their data; also the Director General of Observatories, New Delhi, for granting permission to publish.

Imbricate thrust model of the Southern Uplands of Scotland

FAUNAL and structural evidence^{1–3} suggest that a wide ocean was present between the Southern Uplands of Scotland and the English Lake District, and that during the late Ordovician and the Silurian the Southern Uplands were situated on the continental margin of North America, where the Iapetus Ocean was being subducted. Here we explain the stratigraphical and structural relationships observed in the Southern Uplands by a dynamic model involving sequential accretion of an imbricating sedimentary wedge on to the continental margin. This evolutionary pattern is analogous to those suggested for many modern convergent plate boundaries^{4–15}.

The Southern Uplands has been divided stratigraphically into three units¹⁶ (Fig. 1). The Southern Belt is composed of Wenlock greywackes and shales, some of which contain graptolites¹⁷. The Central Belt consists of greywackes overlying condensed Moffat Shale successions of mid-Ordovician to Llandovery shales, ashes and cherts. In the

Northern Belt, which is entirely of Ordovician age, mafic volcanics, bedded cherts and, in some places, graptolitic shales underlie greywackes. The shales provided Lapworth with the data for his classic work on the use of graptolites as stratigraphic indicators; the seventeen zones of the Upper Ordovician and Lower Silurian have an average thickness of less than 5 m when present in this facies (see Fig. 2).

The general succession resembles many to be found in ocean basins today¹⁸, except that calcareous plankton were absent during the Lower Palaeozoic, and carbonaceous graptolitic shales occupy the position held by calcareous oozes in many modern oceanic sequences.

The rocks in the Southern Uplands have been interpreted as oceanic or trench deposits in the majority of previous plate tectonic reconstructions^{1,2,4,19}, but contrary views have been expressed based on the presence of high velocity rocks at depths of around 15 km below the Southern Uplands²⁰. On close inspection, however, the phase velocities recorded at the Eskdalemuir seismic array²¹ show considerable scatter, but there is a tendency for fast and slow-velocity source positions to be controlled by regional (ENE–WSW) strike. The slow velocities are obtained from positions in directions transverse to strike, and the fast velocities come from directions parallel to strike. It seems possible, therefore, that there is no sharp contact between low and high velocity rocks, and the higher velocities could be derived from metamorphosed Lower Palaeozoic sediments at depth.

Fig. 1 Map of the Southern Uplands showing the location of the seven sequences in Fig. 2.

Our work in the Northern and Central Belts (unpublished) has substantiated previous observations of the importance of strike faults in the Southern Uplands^{22–28}. Investigation (by J.K.L. and W.S.M.) of sections provided across the strike of the Northern Belt by the recent British Gas pipeline on a traverse to the west of the Clyde Valley has shown that, with only minor exceptions, beds dip at high angles and young predominantly to the north-west. Reverse faults are evident in zones of intense imbrication where the condensed basal basalt-chert-graptolitic mudstone units crop out, but they occur less frequently in the greywacke sections. In the Northern Belt, at least three major reverse faults must be inferred between observed zones of radically different stratigraphy (Fig. 2, sections 1–3). The Central and Southern Belt pipeline sections in Annandale (recorded by M.H.E.) showed steeply-dipping greywackes; though sometimes inverted, they were predominantly

Fig. 2 Ordovician and Lower Silurian stratigraphy in the Southern Uplands: seven sections on a north-west/south-east traverse from the Southern Upland Fault in the Biggar area, Lanarkshire to the Moffat area, Dumfriesshire. The vertical scale reflects the ages of the beds. In the Central Belt (sections 4–7) the total thickness of the graptolitic shales and pyroclastic interbeds is up to about 80 m. Greywacke thicknesses in each fault block may be up to several kilometres. All sections are separated by faults (see Fig. 3). Beds with graptolites are linked by horizontal lines. Conodont localities from Lamont and Lindstrom³¹.

younging to the north-west. Lack of stratigraphic evidence precluded recognition of major fault-bounded sequences from the pipeline alone. A combination of this evidence with the well-established regional stratigraphy^{16,17,27,28}, however, shows significant differences in lithology and age of adjacent sequences (Fig. 2). In particular, it is estimated that the 26 graptolite zones of the Ordovician and Lower Silurian have a total duration of 80 Myr, an average of about 3 Myr per zone. The graptolite faunas thus show that the start of greywacke sedimentation differed by about 3–18 Myr between adjacent sections. We conclude that they were originally deposited far apart, and that they have subsequently been brought together tectonically.

Table 1 Deformation phases in the Moffat Shale of the Central Belt of the Southern Uplands

Style	σ_1	Phase
D ₁	335°	Thrusting southwards at a low angle to bedding, associated cleavage and isoclinal folding
D ₂	320°	Rotation of bedding and thrust planes, monocline formation
D ₃	340°	High-angled strike fault formation
D ₄		Wrench faulting
D ₅		Normal faulting

Structural analysis by M.H.E. from a number of Moffat Shale inliers suggests a complex evolution (Table 1). Initial low-angle southward thrusting, associated with some isoclinal folding was followed by rotation involving steepening, the formation of broad monoclines and steeply dipping strike faults. Such deformational sequences may be seen in certain inliers near Moffat such as at Dobb's Linn and Craigmichen, where beds are thrust over others of the same age but of considerable difference in lithology and thickness. Presumably sheet transportation must have been considerable to account for the juxtaposition of such dissimilar strata.

The model proposed here for the Southern Uplands (Fig. 3) is very similar to those suggested for many modern accretionary prisms. Along the Central American Trench⁶ there is imbricate thrusting and associated folding with progressive steepening, followed by uplift; this shows close analogies with the evolutionary development along such margins as those off Japan⁷, Washington and Oregon⁸, the Makran coast of Iran⁹, Peru¹⁰ and the Aleutians¹¹. Recently uplifted accretionary prism sequences are evident in Barbados^{11,12}, Alaska^{13,29} and the Mentawai Islands (Sumatra)¹⁴. In the Southern Uplands, Cockburnland, situated along what now constitutes much of the Northern Belt, became emergent by Upper Llandovery times and was a source of sediment for both the ocean to the south and the Midland Valley basin to the north²⁸. The younging of successive wedges towards the ocean coupled with overall younging of the sequence within each wedge towards the continent is diagnostic of accretionary prisms; this may be used as a test for their recognition in the geological record.

Fig. 3 The Southern Uplands accretionary prism in Caradoc and Wenlock times. Cockburnland was an emergent trench slope break in the Silurian. The numbers 1-7 refer to the sections in Fig. 2. Major faults separate each sequence; in addition, each sequence is affected by many minor faults. Only the known major faults are shown; there may be others, especially in some of the greywacke tracts (for example between sections 2 and 3). The shading at the base of the sections in the Northern Belt represents basalts and cherts, and in the Central Belt it represents shales and occasional cherts. The sediments in the Midland Valley and on the ocean crust to the south are also shaded. The remainder of the rocks are greywackes. The present level of erosion is arcuate to allow for post-Wenlock oversteepening of the prism.

All the evolutionary phases for the accretionary prism are assumed to be diachronous, occurring progressively later to the south. Uplift in the north occurred while accretion was still taking place on the oceanic margin of the Southern Uplands, and while sediments were still being laid down out on the ocean. The oncoming of the greywacke was progressively later to the south (Fig. 2). Similarly, the structural styles are diachronous across the prism; the D₁ to D₃ deformational phases represent only a systematic progression of style as a response to the same tectonic vectors.

With progressive accretion, the ocean margin of the prism migrated about 70 km southwards from a position

close to the Southern Upland Fault in the Llandeilo to the site of the Solway Firth in the Wenlock. Comparison with contemporary examples, such as the Aleutians, suggests that the angle of subduction decreased as the oceanic margin migrated southwards³⁰ (Fig. 3).

Cretaceous and Tertiary dinoflagellates from Seymour Island, Antarctica

THE marine sediments on Seymour Island, north-eastern Antarctica Peninsula, have produced numerous plant, invertebrate, and vertebrate remains over the past 80 yr (ref. 1). These strata have been regarded as Campanian (late Cretaceous) and Miocene. Dinoflagellate assemblages, reported here for the first time, indicate that some of the Cretaceous beds may be older (Senonian) than previously suspected and that the supposed Miocene beds are instead late Eocene and early Oligocene in age. These Eocene-Oligocene strata are the only known marine sediments of that age exposed on the Antarctic Continent.

The first detailed mapping of Seymour Island began in 1973-1974 (ref. 2). The marine sediments on the island are traditionally divided into two main groups: the Snow Hill Island beds of early and medial Campanian (late Cretaceous) based on ammonites³ and the Seymour Island Series of early Miocene age based in part on fossil penguins^{4,5}. The material examined for dinoflagellates comes from four sections (Fig. 1) measured through these strata^{2,6}. The samples were collected principally by W. A. Bryant (US Geological Survey) and T. A. Trautman (Ohio State University) during the 1974-75 season.

The beds at the north-eastern end of the island adjacent to Cape Wiman that have been mapped as Cretaceous² may be

Palaeocene. A single dinoflagellate assemblage from 63 m above the base near the middle of section S-16 is dominated by an undescribed species and includes *Svalbardella australina*, *Hystrichosphaeridium tubiferum*, *Eisenackia*, and *Palambages*. The presence of these species indicates a Palaeocene correlation, although a possible very late Cretaceous age cannot be entirely discounted.

The northern half of the island, with the exception of the area adjacent to Cape Wiman, contains exposures of the supposed Miocene age Seymour Island Series. The 285-m section from the beach to the west edge of the meseta

Fig. 1 Seymour Island ($64^{\circ}15'S$, $56^{\circ}45'W$) and generalised stratigraphic sections. Dots to right of columns represent samples from which dinoflagellates were recovered. The maximum length of Seymour is 20.5 km.

(section S-3) includes the oldest beds exposed in that part of the island. Sediments from the lower 84 m of the section contain a diverse dinoflagellate flora that includes *Aerosphaeridium diktyoplokos*, *Deflandrea fuegiensis*, *Deflandrea macmurdoensis*, *Hystrichosphaeridium tubiferum*, and *Spinidinium aperturum*. Above 84 m occur *Aiorea fenestrata*, *Cyclopsiella*, *Thalassiphora*, and *Tubiosphaera filosa*, in addition to the common forms *Deflandrea macmurdoensis* and *Spinidinium aperturum*. These species indicate a late Eocene–early Oligocene age for the Seymour Island Series. The dinoflagellate succession correlates in part with the flora from the Eocene Río Turbio Formation in southern Argentina^{7,8}, and similarities in species composition to the dinoflagellate assemblages from Deep Sea Drilling Project Site 274 of Leg 28 near the Antarctic coast are evident⁹. Several of the above species have been recovered from glacial erratics at McMurdo Sound^{10–13} and from mud

samples grabbed from the bottom of Ross Sea beyond the Ross Ice Shelf¹⁴. Lower Tertiary sediments that are the source of these erratics and dinoflagellates are not exposed in the McMurdo Sound region although beds which correlate with those on Seymour Island undoubtedly exist deeply buried beneath the continental ice sheet. The dinoflagellate evidence supports Simpson's¹⁵ conclusion that the fossil penguin materials from Seymour Island, presumably from the upper part of section S-3 or its equivalent², are no older than late Eocene and no younger than early Oligocene.

Eastern Cross Valley is thought to be the area from which the plant material that was examined for pollen by Cranwell¹⁶ was collected by the Swedish Antarctic Expedition of 1901–1903. The age of the pollen assemblage was initially reported as early Tertiary with recycled late Cretaceous forms¹⁶ and later re-interpreted as Maestrichtian–Palaeocene¹⁷. Section S-13 was measured in the Cross Valley fault zone. Only two samples (130 and 132 m above base) were examined for dinoflagellates. The lower one has a rich spore and pollen content but only one unidentified dinoflagellate; the upper sample is dominated by *Paralecaniella indentata* which in Australia has a stratigraphic range from Campanian to Miocene¹⁸. Neither of the samples from S-13 provides conclusive information. It is likely, however, that the Cross Valley area contains a number of fault slivers which may include both late Cretaceous and early Tertiary sediments.

Section S-11 in the area mapped Cretaceous³ south of Cross Valley may be Palaeocene. Dinoflagellate assemblages from S-11 include *Chlamydomphorella*, *Hystrichosphaeridium tubiferum*, *Palaeoperidinium*, *Spiniferites ramosa ramosa*, *Svalbardella australina*, *Tanyosphaeridium*, *Palambages* spp., and *Paralecaniella indentata*; the ubiquitous *Deflandrea macmurdoensis* and *Spinidinium aperturum* of section S-3 are absent from S-11.

The southern half of Seymour has been dated by ammonite collections as late Campanian¹⁹ and early-medial Campanian³. Matrix from an unidentified ammonite collected by W. J. Zinsmeister (Ohio State University) from that part of the island (Fig. 1) contains the dinoflagellates *Cyclonephelium distinctum* and *Deflandrea cretacea*, indicating an early Senonian age for the ammonite, thus pre-dating the previous ammonite-based Campanian assignment.

Owing to the discovery of several previously undescribed faults in Cross Valley and to the results from the dinoflagellate investigation that differ from other palaeontological studies, final conclusions about the biostratigraphy and correlation of the southern part of Seymour Island will depend on further detailed mapping; at present the extreme southern part of Seymour Island has not been examined.

The abundant well preserved dinoflagellates of Seymour Island provide a new basis for unravelling what seems to be a more complex geology than anticipated. As the dinoflagellate and stratigraphic succession is studied it will become a standard for correlation of the other plant, invertebrate, and vertebrate remains with the better known and more accessible records elsewhere in the Southern Hemisphere.

In addition to abundant dinoflagellates, every sample examined except the one from S-16 contains a very rich assemblage of spores and pollen including several forms of *Nothofagus* and, from S-3, pollen of Gramineae. This is the first fossil record of grasses from Antarctica. Also, massula of the freshwater fern *Azolla* occur in S-11. These late Cretaceous–early Tertiary spores and pollen grains are unstudied but should provide a history of low latitude Antarctica vegetation during the Palaeocene–Oligocene period of climatic cooling before the formation of the present Antarctic Ice Sheet^{20,21}.

This study was supported by an NSF grant to Northern Illinois University; the field investigations were coordinated

through the Ohio State University Institute of Polar Studies and the Instituto Antártico Argentino.

Temporal characteristics of iconic memory

THE duration of visual persistence (iconic memory) is inversely related, up to a point, to the duration of the inducing stimulus. This suggests that iconic memory can more properly be identified with ongoing neural processes than with the decaying contents of a sensory store. Since the publication of Sperling's influential monograph¹ there has been general agreement that a relatively faithful representation of a visual display remains perceptually available for several hundred milliseconds after the distal stimulus has vanished. This led to the postulation of a short-term visual store, also called iconic memory² or sensory register³, with contents decaying rapidly after the termination of the inducing display. The terms visual persistence or icon are commonly used to refer to the perceptual availability of the decaying contents of the sensory store. Iconic memory is regarded as having temporal combinatorial properties which allow perceptual integration of two or more sequential displays even if separated by a brief temporal gap. Integration in iconic memory was convincingly demonstrated in a study where the subjects were required to identify which element in a briefly-displayed array of 16 alphabet characters had been singled out by a temporally trailing bar marker⁴. Temporal integration has also provided an explanation for some aspects of visual masking⁵ and for temporal integration of patterns whose parts were presented sequentially in time^{6,7}. Here I question the view that iconic memory is a store whose contents begin to decay when the inducing stimulus is terminated. I suggest that the duration of iconic persistence is linked to the duration of visual processes which begin at the onset of stimulation and continue for a given duration, whether or not the inducing stimulus is still on display. This view is based on the finding that the duration of visual persistence is negatively related to the duration of the inducing stimulus.

The experimental technique⁷ used a computer-driven oscilloscopic display (gridless Tektronix 602 equipped with ultrafast P15 phosphor) consisting of a square matrix of 25 dots arranged in five rows and columns. One of the 25 dots, chosen randomly on every trial, was not plotted. The subject, who sat in a dark room, initiated each display with a button press and then reported the matrix coordinates of the missing dot. The matrix was displayed in two successive portions separated by a temporal gap: first, an aggregate of

12 dots, chosen randomly from the matrix, was displayed for a period that varied between 10 and 200 ms, depending on the condition; next, a 10-ms temporal gap was allowed to elapse with no dots shown on the screen; and, finally the remaining 12 dots were displayed for 10 ms.

Figure 1 shows the results for two subjects. Almost identical results were obtained with other subjects and with casual observers in the laboratory. A marked impairment in performance is evident as the duration of the leading display exceeded about 100 ms. The phenomenal appearance of the display should be noted: at the shorter durations of the leading portion all dots in the matrix were perceived simultaneously with no evidence of a temporal gap. At the longer durations the display was seen clearly in two successive portions separated by a significant gap.

Since the experimental task was practically impossible unless the two portions of the display were actually seen as one, it seems likely that some sort of visual persistence was necessary for bridging the temporal gap. But could persistence be attributed to the rapidly decaying contents of an iconic store? Probably not. Bearing in mind that the temporal gap was of the same duration in every condition, and that a 'storage' theory assumes an icon whose strength does not start decaying until the termination of stimulation, it is difficult to see how the briefest (10 ms) display could induce iconic contents capable of bridging a given temporal gap while a much longer display could not.

More plausible inferences about visual persistence are, first, that its duration may be more closely timelocked to the onset than to the termination of the inducing stimulus, and second, that it may be more properly considered to be

Fig. 1 Percentage of errors in identifying the location of a missing dot within a 5 × 5-element dot matrix which was displayed on an oscilloscope in two portions of 12 dots each, separated by a 10-ms gap. The duration of the first portion of the display is shown on the abscissa; the second portion was always 10 ms. The matrix subtended approximately 6° of visual angle. The two portions of the display were equated for brightness through computer-controlled modulation of the oscilloscope's Z-axis. This allowed independent variation of the intensity of each dot in the display. The appropriate intensity levels for each duration of the leading display had been determined separately in a preliminary psychophysical task. Entirely similar results were obtained without brightness-compensation despite some degree of brightness-mismatch between the two portions of the display. Results are for two subjects—M.K. (●) and V.D.L. (○).

a product of ongoing neural processes of finite duration than the contents of a sensory store.

But before pursuing this line of reasoning, an alternative interpretation must be examined. It may be argued that impairment of performance at the longer durations of the leading display (Fig. 1) may have been due not to reduced visual persistence but to the triggering of some form of discontinuity-detection mechanism within the visual system which effectively segregated the two portions of the display one from the other^{6,8}. To examine this alternative, the display sequence was altered so that each of the 24 dots was displayed once only in random sequence at a regular inter-dot interval (with one exception as noted below). If the inter-dot interval is such that the total duration of plotting of the 24 dots exceeds about 120 ms, the matrix appears to have more than one missing element⁷. The observer is thus confronted with a choice among several apparently empty matrix locations which are indistinguishable from the truly empty location. Over 90% of the errors result from confusing the unplotted dot with dots plotted more than about 120 ms before the termination of the display and hence perceptually unavailable⁷.

The procedure of the second study was a modification of that of Hogben and Di Lollo⁷. The inter-dot interval was fixed at 10 ms corresponding to a total (24-dot) plotting duration of approximately 230 ms. In the control condition each of the 24 dots was plotted once only for 1.5 μ s. In the experimental condition each dot was plotted for 1.5 μ s except for the 12th dot which was plotted for 100 ms (Fig. 2). On the assumption that, up to a limit, the duration of visual persistence is inversely related to the duration of the inducing stimulus, it was expected that the sensory persistence of the 12th dot would be briefer in the experimental than in the control conditions. In turn, it was expected that the 12th dot would be erroneously identified as missing more frequently in the experimental than in the control conditions.

Two observers (the author and a student unaware of the purpose of the research) served in five experimental and five control sessions; each session consisted of 100 trials. The error distributions are shown in Fig. 3, separately for each

Fig. 2 Schematic representation of the plotting sequence. Each of the 24 dots was displayed for 1.5 μ s except for the 12th dot which was plotted for 100 ms. The 12th dot remained on view from the time of plotting of the second dot until 10 ms after the plotting of the 11th dot. Its brightness was indistinguishable from that of all other dots through the compensation procedure described in Fig. 1. The order of plotting was randomised on every trial so that every matrix location had an equal probability of being the 12th in the sequence.

Fig. 3 Temporal distribution of errors in the results of the second experiment. Within each graph, the abscissa indicates the ordinal position of each dot within the plotting sequence, irrespective of spatial location; the ordinate shows the proportion of trials on which a dot plotted in the indicated ordinal position was incorrectly identified as missing. ○, Control condition where every dot was plotted for 1.5 μ s; ●, experimental condition where all dots were plotted for 1.5 μ s except the 12th dot which was plotted for 100 ms. *a*, Subject L.D.C.; *b* V.D.L.

observer. Clearly, the probability of erroneously identifying the 12th dot in the sequence as missing was distinctly higher when its physical duration was long than when it was brief. Similar results were obtained with several other observers.

Unlike the first experiment, where perceptual segregation of the two portions of the display might have been possible, the continuous distribution of the dots over the entire plotting interval made segregation an all but irrelevant consideration in the second experiment. The results also deny the possibility that the termination of the 12th dot might have triggered some sort of discontinuity-detection mechanism within the visual system: had this been so, all dots plotted before the termination of the 12th dot would have become perceptually segregated from the remaining dots. On the contrary, the error distribution (Fig. 3) shows that the dots closely preceding or following the 12th dot in the display sequence were confused with the missing dot much less frequently than the 12th dot.

Contrary to most current thinking^{1-4,9} where iconic memory is said to begin at the termination of a display and to fade rapidly thereafter, the present findings suggest that

iconic memory (as distinct from a retinal after-image) begins at the onset of a display and continues only for a given duration (see also refs 10–13). Thus, iconic memory remains available after the termination of a display only if the duration of the inducing stimulus does not outstrip a given maximum duration from the onset of stimulation. This pattern of results strongly suggests that iconic memory may be more properly viewed as the product of neural processes of finite duration rather than as a sensory store whose contents begin to fade when stimulation terminates. The nature of the processes cannot yet be identified, but there is some support for the view that sensory persistence is produced by the activity of coding mechanisms at the level of feature extraction in visual information processing¹⁴. On this view, persistence would continue while the coding mechanisms are active and would cease at the termination of that processing phase, whether or not the inducing stimulus is still on display.

Cuckoo among Lake Malawi cichlid fish

THE family Cichlidae consists of bony, perch-like fish which are found in many of the fresh waters of America, Africa and Asia. In Africa most of the almost 700 species occur in the Great Lakes. Approximately 300 species are known in Lake Malawi and 98% of them are endemic to it. Like cichlids from elsewhere, they have intricate but stereotyped territorial and courtship behaviour, followed by spawning and a period of parental care¹. Substrate spawners lay their eggs on the substratum or a suitable object and both parents guard the eggs and later the developing fry^{1,2}. In Lake Malawi the only known substrate spawner is *Tilapia rendalli* Dumeril, a non-endemic species. Evidence suggests that all other cichlids of Lake Malawi are maternal mouthbrooders. When eggs are laid they are picked up by the females and brooded in the mouth^{1,2}. When fry are ready to emerge the parent releases them at a suitable site and usually remains to guard her brood, recalling them into her mouth in the event of danger^{1,2}. After several days, fry no longer respond to their mother's recall signals and the association is terminated. Although cichlid parents usually guard their fry ferociously it seems that at least one species passes these parental duties on to other species of cichlid.

In May 1976, during diving off Likoma and Chisumulu Islands (Lake Malawi), maternal *Haplochromis polystigma* Regan were found caring for mixed broods: their own offspring, easily recognised because they have adult coloration and markings from the outset, and fry of another species differing slightly in size and markedly in coloration. *Haplo-*

chromis macrostoma Regan and *Serranochromis robustus* Regan were also found guarding mixed broods. The foreign fry appeared to belong in all cases to a single species, and differed sufficiently from the native fry to be readily distinguished. When prompted by divers, the guarding parents always retrieved their mixed broods. On occasion, they collected their own fry with greater facility than the foreign individuals, possibly due to a better response of their own progeny to recall signals.

As mixed broods were found on several occasions with each of the three parental species it is unlikely that foreign fry were included by chance. During the 10-d period at Likoma and Chisumulu Islands, *H. polystigma*, *H. macrostoma* and *S. robustus* parents were not found with pure broods.

Members of a mixed brood of *S. robustus* were caught and reared and the cuckoo was identified in January 1977 as *Haplochromis chrysonotus* Boulenger. *H. chrysonotus* is widespread in Lake Malawi and is a member of the Utaka group, which are plankton feeders³.

When the observations were made, shoals of *H. chrysonotus* brooding eggs or fry in their mouths were common in the surface waters. Surrogate parents were found beneath them on the rocks in 2–10 m depth. How the transfer of fry from *H. chrysonotus* to the foster parents takes place is unknown. The three species of foster parent are all active predators and it is conceivable that *H. chrysonotus* forms part of their diet.

It is easy to understand why *H. chrysonotus* progeny should accept foster parents because fry of maternal mouthbrooding cichlids show a very poor parental recognition response. They will follow and attempt to enter crude models which bear no resemblance to the parent in colour, shape, size or markings^{1,4}. Virtually all that is required to induce following is for the model to be moved in a manner which simulates calling behaviour.

It is not easy to understand why foster parents accept and care for fry markedly different from their own. Laboratory experiments^{5,6} with substrate-spawning cichlids have shown that broods could be swapped or mixed provided the progeny were very similar in age, size and behaviour. Dissimilarity of one or more of these criteria invariably resulted in the foster parent eating the foreign fry. Clearly the success of a cichlid cuckoo depends on accurate timing of introductions to the native brood and a similarity of behaviour. Furthermore, provided *H. chrysonotus* fry become intermingled in the foster parents' brood, then even if the parent were reluctant to accept them she would be unable to remove them. A predatory approach towards a mixed brood would evoke an avoidance reaction in all its members. In such circumstances foreign fry would be protected from the surrogate mother by shoaling with her own fry, and protected from other predators by their foster parent when they are taken into her mouth.

Cichlid fry reared with foster parents have been found to prefer the foster parental species to conspecific mates when placed in choice chambers at sexual maturity⁷. In natural conditions, however, *H. chrysonotus* and the three species of foster parent apparently breed true. It is therefore improbable that foster parents become imprinted on *H. chrysonotus* fry to such an extent as to impair subsequent recognition of conspecific rivals and mates.

Although *H. chrysonotus* brood their own eggs in their mouths, they are cuckoos in the sense that foster parents guard their young. This observation raises questions concerning the significance of the parent-brood relationship, the behavioural mechanism(s) of brood hybridisation, and the role of *H. chrysonotus* as a parent.

I thank the Malawi Fisheries Department, the South African Department of Foreign Affairs and the J. L. B. Smith Institute of Ichthyology, Rhodes University, for

financial support. I also thank P. B. N. Jackson who identified *H. chrysnotus*.

Mode of action of insoluble monolayers on mosquito pupal respiration

THE emergence of resistant species and an increased awareness of the environmental problems associated with the use of insecticides has resulted in a search for alternative methods of mosquito control¹. One possibility is lecithin (phosphatidylcholine), which is lethal to the pupae of many species of mosquito and to some fourth stage larvae, when spread as a monomolecular layer at high surface pressure on the air–water interface^{2,3}. Other analogous water-insoluble surfactants, such as cetyl, stearyl and oleyl alcohol ethers of ethylene glycol are equally effective, and successful trials using several of these monolayers have been carried out on rice fields in Kenya⁴. These have not, however, thrown much light on the mechanism of the anoxic process. Observations by high-speed photography suggested that it is not simply a decrease in surface tension, with consequent wetting of the respiratory trumpet of the insect, but also involves a physical barrier to surface penetration (demonstrated in a 35-mm film available from A.I.M.). We report here the importance of the rheological nature of the monolayer, and show that those exhibiting ‘liquid’ properties at high concentrations form efficient barriers while ‘solid’ monolayers do not. We suggest that liquidity at high surface pressure enables (1) rapid repair of the monolayer after penetration or other disturbance; (2) rapid monolayer transfer to the penetrating trumpet during its displacement from the surface followed by ‘wetting’ and the formation of a bilayer-stabilised water ‘plug’, and (3) complete coverage of the water catchment surface in spite of, for example, projecting vegetation.

We applied 0.5 µg of several natural and synthetic lecithins and several semi-synthetic ethoxylated fatty alcohols as solutions in chloroform–methanol (2:1), to clean air–water interfaces within circular dishes of 5 cm internal diameter, each containing 40 pupae of *Aedes (Stegomyia) aegypti* in 8 cm of water at pH 5.8 and 27 °C. This amount of lipid is slightly in excess of that required to give complete coverage as a monolayer. We ensured that the pupae were submerged during the application and evaporation of the solvent. Differential surface

pressures (π) between the monolayer-covered water and clean water (also containing 40 pupae but treated with solvent only) were measured with a null-point electrobalance to each arm of which was attached a mica Wilhelmy plate about 1 cm wide. This gave the monolayer surface pressure as a function of time, with automatic compensation for solvent effects and pupal exudates (if any). The shear rheological properties of the monolayers were determined qualitatively by observation of movements of talc particles sprinkled on the film and gently subjected to an air jet. The surface pressure–molecular area curves obtained in separate experiments on an automated surface balance were used to observe the physical states of the lipid monolayers⁵.

Table 1 summarises the characteristics of the monolayers and their effects on pupae. The gel–liquid crystal transition temperature of lecithin bilayers (T_c) is the critical temperature for the transition from condensed to expanded monolayer⁶. When $T > T_c$, the monolayer is liquid-expanded at all film pressures up to the collapse point. π_s is the maximum film pressure observed when the monolayers were spread from solution and π_e , the equilibrium spreading pressure, is the pressure achieved by spreading from the pure solid⁶.

Table 1 shows that solid, condensed films do not cause death by anoxia, even at surface pressures close to 49 mN m⁻¹ while liquid-expanded films of similar chemical composition are effective at pressures down to about 40 mN m⁻¹. Previous work established a ‘threshold’ effectiveness at approximately 45 mN m⁻¹ (ref. 3). A simple explanation of the difference between solid and liquid films is that the solid film can readily be broken and partially collapsed by pupae; the hole is not immediately repaired because the lecithin cannot respread spontaneously because the value of π_e is zero^{5,6} and the solid ethoxylate film spreads to only 34 mN m⁻¹. On the other hand, similar breaks in liquid-expanded films are repaired quickly (because $\pi_e \approx 50$ mN m⁻¹), the rate depending on surface viscosity. Thus in the latter case, pupae are always faced with a complete and continuous monolayer at a very high surface pressure; this very high lateral pressure will increase the work required to create a hole in the film and tend to squeeze any trumpets out of the interface. We now consider the mechanism by which such films lead to anoxia of pupae.

In normal conditions, the pupal trumpet breaks surface readily without movement of the pupa other than vertical buoyant rise. Even in the presence of a liquid monolayer at $\pi > 45$ mN m⁻¹, pupae can usually gain access to the atmosphere at the first attempt but in subsequent attempts they struggle vigorously against the film, often concentrating the effort on one trumpet by attacking the surface sideways. When penetration is prevented, the air sac within the trumpet can be seen clearly like a stabilised foam bubble which does not coalesce with the atmosphere. Thus the interior of the trumpet can be represented as a bubble of air enclosed within a hydrophobic layer of material rising towards the surface (Fig. 1A). As the trumpet reaches the surface, water molecules must drain from between the two air phases, a^* and a , for these to coalesce, giving direct access of the respiratory system

Table 1 Characteristics of monolayers

Lecithin (or analogue)	Chain length and degree of unsaturation	T_c (°C)	Monolayer state at 27 °C	π_s (mN m ⁻¹)	π_e (mN m ⁻¹ at 27 °C)	% Pupae dead after 12 h at 27 °C
Egg	Mainly					
Total egg lipids	C ₁₆ ^{18:1}	–15 to –5	Liquid-expanded	50	50	100
Di-oleoyl	—	—	Liquid-expanded	48	48	100
Didecanoyl	C _{18:1}	–22	Liquid-expanded	46	46	100
Dimyristoyl	C ₁₀	< 0	Liquid-expanded	45	—	100
Dipalmitoyl	C ₁₄	23	Liquid-expanded	52	50	100
Distearoyl	C ₁₆	41	Solid, condensed	49	0	0
Dibehenoyl	C ₁₈	58	Solid, condensed	49	0	0
Oleyl monoethoxylate	C ₂₂	75	Solid, condensed	37	0	0
Cetyl/stearyl monoethoxylate	C _{18:1}	—	Liquid expanded	41	39	100
	C ₁₆ ¹⁸ /C ₁₈ ¹⁸	—	Solid, condensed	46	34	0

to the atmosphere. When the air-water interface in contact with phase a^* and the trumpet surface is devoid of surfactant molecules, drainage is rapid and rupture of the thin water film is easy (Fig. 1B); the hydrophobic trumpet is dewetted quickly because the receding contact angle θ_R of clean water is finite. This situation holds whenever the pupa penetrates a monolayer at less than the threshold surface pressure or for the first penetration of a monolayer at $\pi > 45 \text{ mN m}^{-1}$.

If a pupa detaches from a lecithin monolayer at $\pi > 45 \text{ mN m}^{-1}$ the bubble a^* becomes covered with a monolayer at high π and on subsequent contact with the surface the trumpet does not dewet quickly, because the air-water θ_R is zero (Fig. 1C and D). Brooks *et al.*⁷ have shown that θ_R for an aqueous surface covered with dipalmitoyl lecithin on low energy solids such as siliconed glass decreases to zero when $\pi \approx 45 \text{ mN m}^{-1}$ (and tends towards zero when $\pi \approx 40 \text{ mN m}^{-1}$ in the case of octadecanol which is non-ionic and analogous to the ethoxylates); this wetting involves deposition of lecithin at the solid-vapour or solid-liquid interface. Because normal dewetting is thereby eliminated, a thin water film is maintained across the mouth of the trumpet and an air channel cannot be formed easily. In this situation, the thin film of water is analogous to that between air bubbles in a foam and it persists because the highly compressed lipid monolayers retard drainage of water from the film; ultimately a black film could be stabilised by interactions between the two monolayers⁸.

Although some species may penetrate a monolayer several times, progressive deposition of lipid and wetting will occur within the trumpet and it will become more and more difficult for the thickening plug of water (Fig. 1D) to drain in a reasonable time. Electron micrograph studies with *Culex pipiens fatigans* suggest that in such instances layers of surfactants are built up on the 'pedepodial' filaments within the trumpet, presumably destroying their function of resisting water invasion. That such deposits (Fig. 2) may be built-up multilayers of lipid is suggested by the observation that lipid multilayers can be deposited on a low energy surface such as PTFE (ref. 9).

Fig. 1 Normal dewetting of the hydrophobic pupal trumpet. In the absence of surfactant the thin film of water across the mouth of the trumpet is unstable because of the high free energies of the two surfaces. After rupture, the clean water recedes from the trumpet because the receding contact angle is finite (A and B). The effects of an insoluble monolayer with equilibrium spreading pressure $\pi_e > 45 \text{ mN m}^{-1}$ on the interaction of the pupal trumpet with the water surface are also shown. On the first approach (A) and (B) still apply because the air-water interface in contact with air inside the trumpet (a^*) is clean and the trumpet penetrates successfully. On subsequent approaches (C and D) this interface is covered with a monolayer of lecithin so that spontaneous dewetting of the trumpet no longer occurs, the receding angle now tending to zero, while the hydrated bilayer film is stabilised by minimal free energy interfaces.

Fig. 2 *a*, An electron micrograph of the 'pedepodia' structures within a normal *Culex p. fatigans* pupal trumpet. *b*, A similar view of a specimen killed by lipid monolayer anoxia.

Laboratory and field studies indicate that many aquatic organisms ('non-target' in the context of mosquito control) are not killed by monolayers and we believe this to be due to the rather specific mechanism which we describe. Even the larvae of mosquito are not killed directly by monolayers, but are inhibited from surfacing until the dissolved oxygen content of the catchment falls below a critical value overnight¹⁰ when they are anoxiated.

When spread on tropical rice fields at about ten times the amount required for monolayer coverage, natural lipids and the semi-synthetic ethoxylates maintain their full surface pressure for about 1 and 3 d respectively. In both cases the monolayers, with their associated 'lenses' of reservoir material, effectively remove mosquitoes for periods of more than 10 d, after which further application would be required to give complete control.

These observations and our suggested mode of action indicate that natural lipid or other high-pressure monomolecular films afford a method of mosquito control which is more selective, more efficient and more ecologically acceptable than methods involving toxic chemicals. In addition, the physical nature of the mode of action which we have outlined may be less likely to encourage the selection of resistant mutants.

Glutamine synthetase and control of nitrogen fixation in *Rhizobium*

Rhizobium, a bacterium which reduces dinitrogen to ammonia in symbiotic association with leguminous plants, 'fixes' nitrogen while living free¹⁻⁴. Unfortunately, free-living fixation seems to occur only at the end of exponential growth, and no condition is known in which bacterial growth is dependent on reduction of dinitrogen by nitro-

genase (EC 1.7.99.2). Therefore a molecular biological analysis must be indirect. In the unrelated *Klebsiella pneumoniae*, where fixation does occur in culture, nitrogenase expression is regulated by the enzyme glutamine synthetase (GS, EC 6.3.1.2). By analogy, we have isolated GS auxotrophs in *Rhizobium* and screened for nitrogenase activity. We chose *Rhizobium* cowpea 32H1 because it has the highest reported nitrogenase activity, both in culture and in nodules⁵. We found that a glutamine-dependent auxotroph of *Rhizobium* cowpea 32H1, deficient in GS activity, is deficient in nitrogenase activity as well. Therefore GS seems to be involved in the control of nitrogenase expression by *Rhizobium*.

In *K. pneumoniae*, mutants lacking GS activity (*gln*⁻) fail to induce measurable nitrogenase activity^{6,7}. Moreover, constitutive mutants (*Gln*^o phenotype), in which GS activity is no longer repressed by ammonia, are also constitutive for nitrogenase activity. On these grounds GS has been proposed as a positive regulator of nitrogenase.

In enteric bacteria GS has both catalytic and regulatory functions. Different GS assay procedures may yield different results. One assay (the 'transferase' reaction) measures ADP-dependent γ -glutamyl hydroxamate formation⁸. In this reaction the adenylylated form is still partially active. The adenylylated and deadenylylated forms of the enzyme GS, however, respond differently to changes in pH and Mg²⁺ concentration. Therefore quantification of GS levels is difficult unless the state of adenylation of GS is known⁹.

We have used the 'transferase' assay for rhizobial GS. Our finding that a GS auxotroph is deficient in nitrogenase is consistent with a similar regulatory role for GS in *Rhizobium*. We wish, however, to emphasise that little is known about rhizobial GS with regard to parameters such as adenylation and assimilation of ammonia at high and low concentrations.

GS transferase activity in wild type 32H1⁺ is shown in Table 1. Activity was five times higher in M + glutamate than in either M + glutamine or M + ammonia. This

Table 1 Glutamine synthetase activities of *Rhizobium* 32H1 strains

Strain	Growth medium	GS transferase activity (U per 10 ⁷ cells)
32H1 ⁺	M+glutamate	2.0
	M+glutamine	0.41
32H1 <i>gln5</i>	M+glutamate	—
	M+glutamine	0.13
32H1 <i>gln5r</i> 101 (<i>Gln</i> ⁺)	M+glutamate	0.47
	M+glutamine	0.39

To isolate glutamine auxotrophs, cells of 32H1⁺ were grown to 5×10^8 per ml in liquid cultures of YAP medium (0.1% yeast extract, 0.1% arabinose, 7.5mM phosphate, pH 6.3). Cells were incubated in citrate buffer, pH 5.5 containing *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (0.1 mg ml⁻¹) for 1 h at 30 °C and then washed with phosphate buffer, pH 6.3. Mutagenised cells were grown overnight in YAP and then resuspended in a minimal defined medium (M) containing: 0.1% arabinose, 0.8 mM MgSO₄, 0.05 mM CaCl₂, ferric citrate (10 μ g ml⁻¹) and 7.5 mM potassium phosphate, pH 6.3. Glutamate (0.1%) was added as nitrogen source and the culture was incubated at 30 °C for 24 h to deplete amino acid pools. At this time penicillin G (5 mg ml⁻¹) and lysozyme (0.1 mg ml⁻¹) were added and shaking was continued for a further 24 h. Surviving cells (approximately 0.1%) were treated with penicillinase and plated on YAP plus glutamine (0.1%). Among 1,500 colonies tested, three grew only when supplemented with glutamine. The reported experiments were conducted with one of these, *gln5*. GS was assayed by the glutamyl transferase reaction described in the text. 32H1⁺, 32H1 *gln5* or independently isolated revertants growing exponentially at 30 °C in M+glutamate (0.1%) or M+glutamine (0.1%) were collected by addition of cetyltrimethylammonium bromide (0.1 mg ml⁻¹) and centrifuged in the cold. Cell pellets were washed once with 1% KCl, centrifuged and resuspended tenfold concentrated in the same. Assays were performed as before⁹, except that the pH was 7.00, where rhizobial GS transferase activity was a maximum. Twenty-five *Gln*⁺ revertants of *gln5* assayed yielded the same non-derepressible phenotype when grown on M+glutamate as is shown by revertant 101.

Fig. 1 Nitrogenase induction in liquid culture of 32H1 compared with 32H1 *gln5*. Nitrogenase was assayed by acetylene reduction in liquid culture¹⁰. 32H1⁺ and 32H1 *gln5* were grown in YAP, centrifuged, washed with phosphate buffer twice and resuspended in M+glutamate (0.1%), glutamine (0.002%) and NaMoO₄ (10 μ g ml⁻¹). Cultures (3 ml) were injected into 30-ml capped serum bottles; the bottles were evacuated to 0.1 atm and the atmosphere was replaced with 95% argon-5% CO₂ four times in succession. O₂ (0.001 atm) and C₂H₂ (0.1 atm) were injected and cultures were rotated vigorously at 30 °C. Aliquots were withdrawn and plated on YAP + glutamine (0.1%) for cell counts: □, 32H1⁺; ■, 32H1 *gln5*; or assayed gas chromatographically for ethylene production: ○, 32H1⁺; ●, 32H1 *gln5*.

suggests that GS is sensitive to repression by ammonia in *Rhizobium*, as in *Klebsiella*; repression in M + glutamine might result from ammonia formed from hydrolysis of glutamine. (We will present a more complete study of repression by ammonia elsewhere.)

GS levels in the mutant *gln5* can be measured only in repressing conditions (M + glutamine). Table 1 shows that *gln5* had little or no GS activity, although a residual γ -glutamyl hydroxamate formed in the 'transferase' assay.

We cannot tell whether the lesion of *gln5* is in the structural gene for GS or elsewhere. For what follows, the important point is that GS activity in *gln5* is negligible.

Figure 1 shows nitrogenase activity in cultures of 32H1⁺ and 32H1 *gln5*. The mutant had no nitrogenase activity above background. Nitrogenase activity was assayed in liquid cultures¹⁰ by the reduction of acetylene to ethylene^{11,12}. Cells were inoculated at 10⁶ per ml. Before detection of nitrogenase activity colony counts reached 10⁸ per ml and then remained essentially unchanged for up to 10 d regardless of whether acetylene was present for nitrogenase quantification. If the vials were opened to the air, exponential growth resumed after some lag and continued to at least 5×10^8 cells per ml, showing that growth factors, particularly nitrogen, had not been depleted. Glutamine was present at an unusually low level (0.002%) because higher levels inhibit nitrogenase induction in 32H1⁺.

To study the effect of the *gln5* allele on symbiotic nitrogen fixation, 32H1⁺, 32H1 *gln5* and *Gln*⁺ revertants of *gln5* were allowed to nodulate the tropical legume *Macropituleum atropurpureum*. Seedlings nodulated with 32H1⁺ showed high levels of nitrogenase activity whereas there was no detectable activity either in plants nodulated with *gln5* or in uninoculated, un-nodulated plants (Fig. 2). *gln5*-inoculated seedlings grown for a further 14 d as a precaution against slow maturation still had no nitrogenase activity.

Seedlings with effective nodules were green and healthy, whereas ineffectively nodulated seedlings began to yellow

Table 2 Nitrogenase activities and phenotypes of viable *Rhizobium* of *M. atropurpureum* nodules

Strain inoculum	Viable cells of <i>Rhizobium</i> * per nodule	Phenotypes*		Nitrogenase activity†
		Gln ⁺ (%)	Gln ⁻ (%)	
32H1 ⁺	7.0 × 10 ⁶	100	—	204
32H1 <i>gln5</i>	5.8 × 10 ⁶	83	17	<1
r101 (Gln ⁺)	6.1 × 10 ⁶	100	—	112
r102	3.6 × 10 ⁶	100	—	<1
r111	8.0 × 10 ⁶	100	—	<1
r113	3.2 × 10 ⁶	100	—	<1
r114	4.1 × 10 ⁶	100	—	86
r16L	5.3 × 10 ⁶	100	—	<1

Seedlings were grown and nodulated with the given strains of *Rhizobium* 32H1⁺, 32H1 *gln5*, and Gln⁺ revertants as described in Fig. 2. Assays for nitrogenase were conducted as described in Fig. 2. Nodules were excised, immersed momentarily in ethanol, then in 3% H₂O₂ for 5 min, crushed in 1.0 ml of phosphate buffer, pH 6.3 and plated on YAP and YAP + glutamine (0.1%) for viable cells of *Rhizobium*.

*Mean number of six nodules.

†Net activity in nmol of ethylene produced per h per nodule minus that produced by uninoculated, un-nodulated seedlings.

due to acute nitrogen starvation. Both ineffective and effective nodules were then crushed and plated for counts of viable *Rhizobium* with both Gln⁻ and Gln⁺ phenotypes. We were surprised that nodules resulting from *gln5* inoculation yielded viable *Rhizobium* in a mixture of both phenotypes, with Gln⁺ predominating (Table 2).

Nodulation with both 32H1⁺ and 32H1 *gln5* was repeated with various amounts of glutamine (0.01–1.0%) added to the seedling media. No nodules were seen on plants inoculated with either strain in the presence of added glutamine. But between one and five nodules per plant eventually developed during the next 14–28 d. As expected, nodules produced from *gln5* inocula had no nitrogenase activity. Again, aseptic crushing and plating for viable *Rhizobium* revealed populations with mixed Gln⁻ and revertant Gln⁺ phenotypes. Therefore *gln5* might itself nodulate and the Gln⁺ colonies represent simply accumulated revertants. Alternatively, *gln5* might be deficient at some stage of nodulation at which reversion to prototrophy is required. In this case *gln5* would only passively inhabit nodules formed by revertants.

Fig. 2 Nitrogenase activity of *M. atropurpureum* nodules. Seeds were surface sterilised in hypochlorite solution (2.5%) for 30 min, sprouted and placed in 70 × 25-mm tubes with filter paper supports. Seedlings were grown in nitrogen-free liquid medium¹⁷ inoculated with 10⁶ exponentially growing 32H1⁺ (○), 32H1 *gln5* (●) or 32H1 Gln⁺ revertant r101 (□) 7d after germination. After 28 d of growth at 29 °C with a constant 14-h photoperiod, well-nodulated seedlings were capped and injected with C₂H₂ (0.1 atm). Aliquots were withdrawn periodically and assayed for ethylene production by gas chromatography^{11,12}. No ethylene production was observed in uninoculated, un-nodulated seedlings or *gln5*-nodulated seedlings. Activities are given per effective nodule, which was determined by subsequently excising individual nodules and assaying for ethylene production.

In culture, 32H1 *gln5* reverts to prototrophy at a rather high frequency of 1×10^{-5} per cell per generation. Six such independently isolated Gln⁺ revertants of *gln5* were tested for nodulation and activity (Table 2). Two gave nodules that reduced acetylene at rates similar to 32H1⁺ nodules. The remaining four gave nodules that looked healthy but had no detectable nitrogenase activity. This suggests that there are two classes of Gln⁺ revertants: those that regain both catalytic and regulatory activities, and those that regain catalytic activity only. (We have no selection for revertants that regain regulatory activity only.)

These results indicate that GS plays a role in the regulation of nitrogenase activity in both free-living *Rhizobium* and bacteroids, although the mechanism is still unclear. Kondorosi *et al.*¹³ have isolated a glutamine-requiring derivative of the 'fast-growing' species *R. meliloti* 41 his⁻ from among the revertants able to grow on D-histidinol. This glutamine auxotroph yields nodules on *Medicago sativa* which do not have nitrogenase activity, a finding similar to our own. The results of Brown and Dilworth¹⁴ with bacteroid preparations suggest that glutamine synthetase–glutamate synthase-directed ammonia assimilation does not occur in the bacteroid, but rather in the associated plant cell where the same two plant enzymes are present at high levels. These plant extracts also had NAD- or NADP-linked glutamate dehydrogenase activities. Bergerson and Turner¹⁵ showed that all ¹⁵N₂ reduced by *R. japonicum* bacteroids appeared rapidly as ¹⁵NH₄⁺ in supernatant fractions, supporting the involvement of plant ammonium assimilatory enzymes in fixation. O'Gara and Shanmugam confirmed that 94% of the ammonium ion produced by nitrogen fixation in free-living *R. japonicum* is exported as ammonium ion¹⁶.

In both free-living and bacteroid states, rhizobial GS seems to be present during fixation at low levels, insufficient to utilise all the ammonium ion produced by nitrogenase. Because bacteroids are inviable differentiated forms, rhizobial GS might be involved in shutting off the assimilation of bacteroid ammonia as part of the overall shift in nodule metabolism from bacterial to plant cells.

We thank William Scowcroft for seeds of *Macropitileum*, Harry Meade for helpful discussions and Adam Kondorosi for discussion and communication of results. This work was supported by a US National Research Service Award to R.A.L. and grants from the NSF and American Cancer Society to E.R.S.

Nitroso group exchange as a way of activation of nitrosamines by bacteria

MUTAGENIC compounds and most carcinogens are thought to interact either directly or through metabolic activation processes with DNA to alter and damage the double helical structure. Bacteria defective in some aspect of DNA repair or recombination are in general much more sensitive to mutagenic and carcinogenic agents than the parent strains. Several bacterial test systems^{1,2} have been developed to assay for carcinogenic activity based on the premise that most carcinogens are mutagens in the proper conditions. One of the most widely used bacterial screening systems has been developed by Ames *et al.*¹ based on mutational reversion to prototrophy of a sensitive strain of *Salmonella typhimurium*. We have developed a screening system using *rec⁻ Escherichia coli* based on the lethal nature of unrepaired DNA³⁻⁵.

During the development of this screening system we discovered that our test bacteria, a *recB⁻ recC⁻* (*recBC*) strain obtained from A. J. Clark, Berkeley, California, was very sensitive to a mixture of 2-acetyl aminofluorene (AAF) and dimethylnitrosamine (DMN), neither of which alone

Fig. 1 Alkaline sucrose gradient analysis of *E. coli* AB1157. Cultures in exponential growth were labelled with ³H-thymidine, 3 µCi ml⁻¹ (specific activity 50 Ci mmol⁻¹) at 37 °C for 1 h in the presence of 2-deoxyadenosine, 250 µg ml⁻¹. Bacteria were then centrifuged, resuspended in 0.1 M phosphate buffer (pH 7.0) and treated with DMN and/or AAF for 20 min. They were then washed twice to remove the carcinogens and resuspended in 0.1 M phosphate buffer (pH 7.0). Following this, 50 µl (~10⁸ cells) were layered gently on 0.15 ml lysing solution (0.15 N NaOH, 0.40 M NaCl, 0.01 M Na-EDTA and 0.3% sarcosyl) placed on top of 4.3 ml alkaline sucrose gradient (5-20% sucrose, 0.9 N NaOH, 0.1 M NaCl and 0.001 M Na-EDTA) and a shelf of 0.5 ml 70% sucrose. The gradients were allowed to stand for 1.5 h or 90 min at room temperature to ensure complete lysis of cells and then centrifuged for 1 h at 40,000 r.p.m. in a SW65 rotor in a Beckman L-65 ultracentrifuge. Eight drop fractions were collected from each gradient and sample counted in a Triton 100-toluene fluor. ●, AAF 25 µg ml⁻¹; □, DMN 2.5 × 10⁻¹ µg ml⁻¹; ○, AAF 25 µg ml⁻¹ plus DMN 2.5 × 10⁻¹ µg ml⁻¹.

Fig. 2 Alkali sensitivity of bacterial DNA as a result of exposure of bacteria to AAF plus DMN. Using the procedures given in Fig. 1, a number of alkaline sucrose gradients were analysed in which the AAF concentration was kept constant at 25 µg ml⁻¹ and the DMN concentration was varied from 2.5 × 10⁻³ to 2.5 × 10⁴ µg ml⁻¹. The ratio of the molecular weight of the DNA of bacteria treated with AAF plus DMN (*M* experimental), to the molecular weight of the untreated control (*M* control) or to the molecular weight of the bacteria treated with AAF or DMN alone was obtained from the relationship:

$$\frac{\text{Distance}_1}{\text{Distance}_2} = \left\{ \frac{M_1}{M_2} \right\}^{0.4}$$

as developed by Studier⁶.

had any effect on the growth of JC5519 (*recBC*). In the presence of 25 µg AAF, the assay could detect as little as 2 × 10⁻² µg DMN without the requirement for metabolic activation which is normally required for DMN. Was this synergistic effect acting in a 'classical' manner on the genome of the bacteria?

Cells of strain AB1157 (the parental strain isogenic with JC5519), whose DNA had been radioactively labelled, were exposed to AAF, DMN and a mixture of AAF and DMN, then lysed on top of an alkaline sucrose gradient and sedimented⁶. Figure 1 presents the results of such gradients which show quite clearly that the combination of AAF and DMN produce alkali-labile lesions (single-strand breaks) in DNA. On the other hand, AAF and DMN alone have no effect on the DNA of the bacteria as observed in alkaline gradients with control bacteria. If the AAF concentration is kept constant and one varies the DMN concentration, the fragment size as observed in alkaline sucrose gradients first decreases as the DMN concentration increases, reaches a minimum size and then increases as shown in Fig 2. At high levels of DMN the combination of AAF and DMN has no effect on the bacterial DNA probably due to cytotoxic effects.

To explore the hypothesis that a bacterial enzyme was involved in this interaction between AAF and DMN, we incubated bacterial extracts from both AB1157 (parent strain) and JC5519 (*recBC*) with AAF and DMN, and tested them with the Ames tester systems. AAF and DMN without microsomal activation have a negligible effect in producing revertants in the *his⁻ S. typhimurium* tester strain; however, in the presence of sonicated bacterial extracts from AB1157 or JC5519, the combination of AAF and DMN became mutagenic in the standard Ames assay (Table 1). As a next step, after incubation of AAF and DMN with a sonicated cell-free bacterial preparation, we extracted the reaction mixture with methylene chloride, evaporated the methylene chloride fraction to dryness, and dissolved the residue in DMSO. This DMSO extract was also active in producing revertants in *S. typhimurium*. These results are presented in Table 1. In Fig. 3 we have plotted the results from a number of assays with the Ames tester strain; the AAF concentration was kept constant and the DMN concentration varied in the presence of JC5519 bacterial extract. The number of revertants rise with DMN

Table 1 Mutagenic activity of cell-free preparations of *E. coli*, AAF and DMN, using *S. typhimurium* TA98

Compounds of mixture	Mutation ratio TA98
1 AAF+DMN+JC5519 prep	2.8
2 AAF+DMN	1.0
3 DMN+JC5519 prep	1.0
4 AAF+JC5519 prep	1.0
5 AAF+DMN+JC5519 prep (heated)*	1.0
6 AAF+DMN+JC5519 Prep (pronase treatment)†	1.0
7 AAF+DMN+AB1157 prep	1.7
8 AAF+DMN+CH ₂ Cl ₂ extract‡ of JC5519	2.3
9 AAF+benzylphenyl nitrosamine+JC5519 prep	2.5
10 AAF+nitroso-pyrrolidine+JC5519 prep	2.4

E. coli JC5519 were grown overnight on nutrient broth, and collected by centrifugation at 4,000g for 15 min. The bacteria were resuspended and washed twice in phosphate buffer (0.1 M, pH 7.0) and finally suspended in 50 ml to give about 10⁹ cells ml⁻¹. The cell suspension was sonicated at full power in a Bionsonik sonicator for 5 min, and cooled in an ice bath. The sonicated preparation was centrifuged three times at 4,000g for 15 min to remove intact bacteria. The final supernatant was used for subsequent experiments. The protein concentration of the preparation was routinely 2.0 mg ml⁻¹ by Folin-Lowry.

To measure the number of *Salmonella* revertants, 1.0 ml of the sonicated *E. coli* preparation, 2.5 µg DMN and 25 µg AAF were incubated for 15 min at 37 °C. The reaction mixture is then mixed in 3.0 ml 0.75% minimal histidine soft-top agar and 10⁶ cells of *S. typhimurium* TA98 of Ames¹ are added. The mixture is poured over minimal agar plates and incubated at 37 °C for 48 h. The mutation ratio is the number of colonies on the experimental plate to the number of colonies on a control plate which is inoculated with the same number of tester bacteria.

*Cell-free extract heated for 15 min in boiling water bath before incubation with DMN and AAF.

†One ml of cell-free extract pre-incubated with 0.1 mg Pronase 20 min before addition of DMN and AAF.

‡DMN (2.5 µg), AAF (25 µg) and 1 ml cell-free extract of *E. coli* were incubated for 15 min. CH₂Cl₂ (5 ml) was added, the mixture shaken, the phases separated after standing 10 min and methylene chloride phase-evaporated to dryness under a stream of N₂; the residue was dissolved in 1.0 ml DMSO and added to 3.0 ml soft-top agar with 10⁶ cells of TA98 and poured over minimal agar plate in a standard Ames test.

concentration and then decrease with higher concentration of DMN (Fig. 3a). A similar curve was obtained by varying the AAF concentration at constant DMN concentration (Fig. 3b).

Nitrosamides are known not to require activation⁷ by liver microsomal enzymes and are capable of reacting directly with DNA. It is possible that these observations reported here (Figs 1 and 2; Table 1) are the result of a nitroso group exchange reaction in which the nitroso group is transferred from the nitrosamines to the amide moiety of AAF. To gain support for this hypothesis an experiment (Table 2) was carried out in which AAF was replaced with a

Experimental conditions as described in Table 1, except for the substitution of various amides instead of AAF.

**Fig. 3** Mutation ratio as a function of concentration. *a*, AAF held constant at 25 µg ml⁻¹ and DMN varied from 0.5 to 3.5 µg ml⁻¹. *b*, DMN held constant at 2.5 µg ml⁻¹ and AAF varied from 5 to 30 µg ml⁻¹. Procedure as given in Table 1.

series of other amides. Mutagen activity was observed with urea, a series of dipeptides and DMN in conjunction with the sonicated bacterial extract of JC5519, but no revertants were formed when amino acids or aminofluorene were substituted for AAF.

We believe that these observations may have importance in understanding the role of nitrosamines and the cause of cancer. *E. coli* is a common enteric bacteria, widely distributed in the environment and nitrosamines can be formed in a variety of circumstances. In the presence of amides of many types, highly reactive nitrosamides can be generated which may enter adjacent cells and cause mutation and possibly transformation to the neoplastic state. In this regard we have been able to detect in faecal flora the nitroso exchange reaction and we are exploring this reaction as a possible cause of colorectal cancer.

Mast cell histamine and cell dehydration thirst

RAT mast cells, which synthesise and secrete the dipsogenic amines, histamine and 5-hydroxytryptamine (5-HT), are particularly abundant around small blood vessels and are known to be very sensitive to variations in tonicity¹. Hypotonic solutions cause their massive degranulation²⁻⁴, release amines from their granules^{5,6} and increase urinary histamine excretion⁷. Hypertonic solutions cause mast cell degranulation⁸ and shrinkage⁹. We report here evidence which suggests that the mast cell is an osmolar receptor and that histamine participates in the afferent link of the drinking behaviour elicited by hypertonic NaCl.

Male rats (300–320 g) were housed individually, and maintained on a 12-h dark-light cycle with continuous access to food pellets and tap water, except during the drinking tests when distilled water was used and food was removed. The drinking stimuli were the intraperitoneal (i.p.) injection of 3% NaCl (2.5 ml per 100 g)^{10,11} and the intravenous (i.v.) injection of 2 M NaCl (0.5 ml per 100 g)¹².

It is well known that the intraperitoneal injection of distilled water results in the depletion of mesenteric mast cells, whereupon they are replaced only slowly, regeneration becoming complete only about 6 weeks later^{4,13}. As can be seen in Fig. 1, the administration of 3% NaCl i.p. to rats injected 24 h earlier with distilled water (7.0 ml per 100 g i.p.) to deplete peritoneal mast cells, resulted in a marked reduction in their water intake during the first 2 h, although this difference was considerably reduced after 24 h (Table 1).

These data suggest that the peritoneal mast cell could be involved in the drinking response elicited by the intraperitoneal administration of 3% NaCl, but do not exclude the possibility that this is due to their anatomic disruption by the locally injected hypertonic solution.

The postulation of the peritoneal mast cells as an osmo-receptor requires the demonstration that peritoneal mast cell-depleted animals drink less in conditions of acute dehydration when the hypertonic NaCl load is administered by any other route.

Rats were anaesthetised with ether and the external jugular vein catheterised as described by Fitzsimons¹² for the intravenous injection of hypertonic solutions in unrestrained animals. When hypertonic NaCl was administered by this route, the drinking response was also significantly reduced in rats injected intraperitoneally with distilled water, 24 h earlier (Table 1). In fact, there were no differences between the amounts of water drunk by rats injected intraperitoneally or intravenously with hypertonic NaCl, either in the control or in the peritoneal mast cell-depleted groups.

Assuming that distilled water could alter other cellular structures in the mesentery besides disrupting the mast cells, we used disodium cromoglycate (DSCG), a drug that inhibits the release of histamine from the rat mast cell^{14,15}.

Fig. 1 Cumulative water intake ($\pm$ s.e.) for control rats (light bars), rats pretreated with intraperitoneal distilled water to deplete peritoneal mast cells (dark bars), and rats pretreated with DSCG (striped bars), after the injection of 3% NaCl 2.5 ml per 100 g i.p. * $P < 0.01$; ** $P < 0.005$; *** $P < 0.001$; **** $P < 0.0005$. The t test has been applied to control compared with distilled water and control compared with DSCG groups.

The administration of DSCG (95 mg kg⁻¹ i.p.) 5 min before injection of 3% NaCl i.p., resulted in a marked inhibition of drinking, of the same magnitude as that observed with the distilled water pretreatment (Fig. 1). As in the previous experiments, the differences were blurred after 24 h (Table 1). Increasing the dose of the drug (up to 190 mg kg⁻¹) did not result in further inhibition of drinking. Neither distilled water nor DSCG depressed or inhibited the drinking response to other dipsogenic stimuli (Table 2). These results indicate that the peritoneal mast cell is in fact involved in the detection of osmolarity changes in the body fluids.

5-HT exerts its dipsogenic effect through the release of kidney renin and the plasmatic generation of angiotensin¹⁶. As thirst elicited by hypertonic solutions is not mediated by the renal renin-angiotensin system^{10,11,17,18}, it seemed unlikely that mast cell 5-HT would be responsible for the drinking behaviour induced by highly concentrated NaCl solutions. As expected, pretreatment with the 5-HT antagonist, methysergide 2 mg kg⁻¹, which blocks 5-HT receptors without evidence of stimulation¹⁹, did not have any effect on the drinking response elicited by hypertonic NaCl (cumulative intake of water after 2 h: controls, 9.3 ± 1.0 , $n=17$; methysergide, 8.9 ± 0.5 , $n=4$).

On the other hand, intraperitoneally injected histamine induces drinking in intact and nephrectomised rats²⁰, which suggested that the hypertonic NaCl thirst could be mediated

Table 1 Effect of peritoneal mast cell depletion and DSCG on rats injected with hypertonic NaCl

	30 min	60 min	2 h	24 h
3% NaCl i.p.	6.43 $\pm$ 0.63 (22)	8.24 $\pm$ 0.66 (27)	8.98 $\pm$ 0.77 (27)	20.55 $\pm$ 2.17 (11)
2 M NaCl i.v.	8.05 $\pm$ 1.63 (10)	9.55 $\pm$ 1.58 (10)	10.30 $\pm$ 1.46 (10)	26.00 $\pm$ 3.65 (10)
DW + 3% NaCl i.p.	2.63 $\pm$ 0.28 (28)	3.65 $\pm$ 0.38 (33)	4.77 $\pm$ 0.52 (33)	18.20 $\pm$ 2.00 (21)
DW + 2 M NaCl (i.v.)	2.64 $\pm$ 0.88 (11)	3.05 $\pm$ 0.92 (11)	3.77 $\pm$ 1.04 (11)	20.91 $\pm$ 1.63 (11)
DSCG 95 mg kg ⁻¹ + 3% NaCl i.p.	1.95 $\pm$ 1.01 (10)	4.20 $\pm$ 1.39 (10)	4.95 $\pm$ 1.39 (10)	17.20 $\pm$ 3.60 (10)
DSCG 190 mg kg ⁻¹ + 3% NaCl i.p.	2.38 $\pm$ 1.00 (8)	4.75 $\pm$ 1.52 (8)	5.13 $\pm$ 1.40 (8)	16.13 $\pm$ 4.30 (8)

The amount of water drunk (mean $\pm$ s.e.) by rats injected intraperitoneally intravenously with hypertonic NaCl, pretreated with distilled water (DW, i.p.) to deplete mast cells, 24 h earlier, and with disodium cromoglycate (DSCG), 5 min earlier. For experimental details see text. Number of rats given in parentheses.

Table 2 Effect of distilled water, DSCG, and H₁ and H₂ antihistamines on the drinking induced by different thirst stimuli

Pretreatment	Thirst stimuli			
	24-h water deprivation (30 min CIW)	Isoprenaline 0.247 mg kg ⁻¹ s.c. (2 h CIW)	3% NaCl i.p. 2.5 ml per 100 g i.p. (2 h CIW)	Histamine 10 mg kg ⁻¹ i.p. (45 min CIW)
Control	8.5 ± 0.8 (10)	9.0 ± 1.0 (6)	8.9 ± 0.7 (27)	4.2 ± 1.2 (8)
DW 7.5 ml per 100 g i.p.	8.4 ± 0.3 (10)	7.5 ± 1.1 (12)	4.7 ± 0.5 (33)	6.8 ± 1.5 (5)
DSCG 95 mg kg ⁻¹	10.6 ± 1.1 (10)	8.9 ± 1.6 (5)	4.9 ± 1.3 (10)	6.1 ± 0.7 (8)
Diphenhydramine 40 mg kg ⁻¹	0 (10)	0 (10)	0 (10)	0 (10)
Mepyramine 32 mg kg ⁻¹	2.7 ± 1.4 (6)	2.3 ± 2.2 (4)	1.8 ± 0.8 (5)	0 (5)
Metiamide 50 mg kg ⁻¹	10.5 ± 1.0 (10)	7.2 ± 2.2 (7)	2.0 ± 0.4 (7)	1.0 ± 0.3 (7)

The cumulative water intake (mean ± s.e.) of rats pretreated with distilled water (DW) 24 h before the start of the water deprivation period, DSCG i.p. 5 min before, and diphenhydramine, mepyramine and metiamide, 10 min before the administration of the other stimuli and the availability of drinking water. Number of animals given in parentheses.

by histamine released from the peritoneal mast cells. The drinking induced by intraperitoneally injected histamine has been reported to be partially inhibited by the pretreatment with diphenhydramine 40 mg kg⁻¹, an antihistamine drug which blocks H₁ receptors²¹. When we pretreated with diphenhydramine 40 mg kg⁻¹ i.p. 10 min earlier, however, we completely abolished the water intake induced by 3% NaCl i.p., both in normal and nephrectomised animals, after 2 h, and markedly diminished the cumulative water intake after 24 h (Table 2). As it is well known that H₁ antihistamines also show anticholinergic activity^{19,22} and that diphenhydramine is the best known member of this group of drugs, we tried to discriminate between a specific antihistamine effect or a reduction of water intake due to the inhibition of cholinergic synthesis essential in the drinking response¹⁷. As can be seen in Table 2, diphenhydramine also abolished thirst induced by isoprenaline 0.247 mg kg⁻¹ subcutaneously, histamine 10 mg kg⁻¹ i.p., and water deprivation (24 h). These results showed that diphenhydramine is a nonspecific inhibitor of drinking in the rat.

Mepyramine 32 mg kg⁻¹, an H₁ antihistamine which is 40,000 times more active against histamine than acetylcholine²², reduced markedly and to the same extent the drinking induced by 3% NaCl, water deprivation (24 h),

histamine and isoprenaline (Table 2). These data, obtained with two H₁ antihistamines with different amounts of anticholinergic activity, suggested that either H₁ receptors were not involved in the histamine-induced thirst or that the administration of H₁ blockers was useless because they always inhibit drinking by a central effect.

We therefore tried the H₂ receptor blocker, metiamide, which shows practically no penetration into the central nervous system²³. As can be seen in Fig. 2, this H₂ antihistamine did not inhibit water intake induced by water deprivation (24 h) and isoprenaline, but blocked almost totally the drinking induced by 3% NaCl i.p. and histamine (Table 2).

Our experiments show that the reduction in the number of mesenteric mast cells and the blockade of mast cell secretion by DSCG reduce significantly the intake of water following the administration of hypertonic NaCl. This effect is most evident 2 h after the intraperitoneal or intravenous injection of the Na load, but is insignificant after 24 h. This was to be expected, as distilled water only destroys the mesenteric mast cells, leaving the rest of the mast cell complement of the body intact, and DSCG is rapidly eliminated¹⁴.

These experiments suggest that the mesenteric rat mast cell has a role in the detection of changes in tonicity of the body fluids. The mast cell is endowed with some of the characteristics that can be expected to be present in an osmotic receptor: perivascular distribution; high sensitivity to changes in tonicity; the ability to synthesise and release amines which induce drinking behaviour and a peculiar mechanism of secretion which involves the endocytosis of extracellular fluid²⁴⁻²⁶; and the eventual exchange of extracellular Na⁺ for histamine within the intracellular storage granules without exocytosis, as suggested by Foreman *et al.*²⁷.

The inability of methysergide to inhibit thirst and its abolishment by metiamide in rats injected with 3% NaCl i.p. indicates that histamine is the mast cell amine involved in the triggering of the drinking response induced by a hypertonic load through the activation of an H₂ receptor.

Histamine induces thirst in the nephrectomised rat²⁰. This shows that the dipsogenic effect of histamine is not wholly mediated by the release of kidney renin and the plasmatic generation of angiotensin, and demonstrates the existence of another mechanism(s) able to convey to the central nervous system specific signals of thirst induction.

Studies using ¹⁴C-histamine have shown that it can cross the brain-blood barrier, even if in limited amounts²⁸. However small, these amounts of histamine might be of physiological importance, since, when applied directly into the hypothalamus, as little as 50 ng histamine can elicit a drinking response²⁹. The fact that metiamide, which does not cross the brain-blood barrier, inhibits both the drinking induced by histamine and hypertonic NaCl i.p., suggests that histamine triggers peripheral stimuli which reach the brain eliciting thirst.

Abdominal vagotomy produces severe deficits in drinking

Fig. 2 Influence of metiamide on the cumulative amount of water drunk by (a) rats deprived of drinking water for 24 h and after the injection of (b) 3% NaCl 2.5 ml per 100 g i.p.; (c) isoprenaline 0.247 mg kg⁻¹ s.c., and (d) histamine 10 mg kg⁻¹ i.p. The vertical bars are twice the s.e. Δ , Control; $\blacktriangle$, metiamide 50 mg kg⁻¹ i.p. 10 min before the rats were allowed access to drinking water (a) or 10 min before injection of the drugs (b, c and d).

behaviour in response to hypertonic NaCl, that are not reproduced by the administration of peripheral anticholinergic drugs³⁰. These data suggest that the critical lesion is the loss of afferent vagal stimuli. It is tempting to speculate that these vagal afferent stimuli are triggered by histamine, through an H₂ receptor. Experiments to test this hypothesis are in progress.

We thank Dr F. T. Herrick (Pharmaceutical Division, Fisons, Loughborough, UK) for disodium cromoglycate, and Dr R. W. Brimblecombe (Smith, Kline & French Institute, Welwyn Garden City, UK) for metiamide. The mepyramine and histamine used were a gift from Professor H. García-Arocha. The diphenhydramine was kindly provided by Dr M. Ibarra (Parke-Davis, Venezuela) and methysergide by Drs H. Weidman and H. Friedli (Sandoz A.G., Basel). The technical assistance of Mrs Angélica Arancibia and the patient help of Ms Emilia Perez Ayuso are acknowledged. This research was partially supported by a CONICIT (Venezuela) grant to D.J.G.

Regulation of acid proteases during growth, quiescence and starvation in normal and transformed cells

CELL protein exists in a continual but variable state of turnover and the total protein content is the net result of the relative rates of synthesis and degradation. Cell growth is the net accumulation of protein, and although the relative contribution of each process is still uncertain the cessation of cell growth could be the result of a decrease in synthesis¹ and/or an increase in degradation². We report here that cessation of growth and starvation in normal cells is accompanied by a large increase in acid protease activity;

however, transformed cells which fail to stop growing also fail to elevate the enzymes responsible for hydrolysis of the great majority of peptide bonds.

When the culture medium is partially depleted of either essential nutrients³ or macromolecular serum growth factors⁴, the cell which retains its growth control will cease proliferation, and enter the G₀ (or extended G₁) phase of the cell cycle, where it can survive for prolonged periods in concentrations of these requirements less than those necessary for cell division. Some of the events which have been observed in response to deprivation of either nutrients or serum factors have been collectively called the 'pleiotypic response'⁵, and an analogous set of events in nutrient-deprived bacteria is known as the 'stringent response'⁶. Among the fundamental events in these starvation responses in both prokaryotes and eukaryotes is an increase in the rate of general cell protein degradation^{5,6}; however, the mechanisms of rapid and long term alterations in proteolysis have remained unknown. The function of the elevation in protein degradation during starvation is the maintenance of amino acid pools as a source of metabolic energy and as precursors for essential protein synthesis.

Whereas the rate of protein degradation is increased during cell starvation, there is now ample evidence that it is decreased during cell growth. As determined by the extracellular release of incorporated radiolabelled amino acids from cell protein, decreased proteolysis as well as increased synthesis contributes to the net gain of protein in several cell types, as observed *in vitro* and *in vivo*⁷. In contrast to the case of the increase in proteolysis during starvation, the cellular logic of the decrease during proliferation is uncertain, and space does not permit discussion of possibilities.

It is helpful for purposes of the present investigation to organise the above observations of the eukaryotic cell into three roughly distinguishable levels of protein degradation corresponding to three cellular conditions of proliferation, quiescence under adequate nutrition, and quiescence under starvation. The resting cell under adequate nutrition degrades its protein at a rate of approximately 2–3% h⁻¹ (ref. 7). Reports of this value, the quantitative extent of the decrease during proliferation and increase during starvation, vary considerably among different cells and tissues and are occasionally contradictory due in part to experimental difficulties in measuring protein degradation.

Figure 1 shows the simultaneous variation in cathepsin D activity, cell growth, and thymidine incorporation in 3T3 cells grown with and without changing the medium. When grown without medium change, cells proliferated logarithmically until d 4; growth then slowed; and at d 8 there was no increase in cell number. Changing the medium on d 4 caused the characteristic stimulation of DNA synthesis and cell growth shown in Fig. 1a, and final cell saturation density was six to seven times that of the unchanged cultures. Cathepsin D activity per cell in those cultures in which the fluid was not changed, increased 10–15-fold from its initial value in logarithmically growing cells and increased five to sixfold in those cultures in which the fluid was changed. Stimulation of growth caused the transient decline in protease activity shown in Fig. 1b, the extent of which depends on the persistence of the activity (enzyme half life) as well as the regulation of its synthetic rate. Thus, in the three different cellular condition of logarithmic growth, quiescence under adequate nutrition, and quiescence under a deficit of nutritional or hormonal factors, there are three different levels of the acid proteases (Fig. 1b). The identity of the factors depleted from the medium which cause the elevation in acid protease activity, is being investigated.

Those starving transformed cells which have completely lost their growth control, such as the Simian virus (SV)-transformed SV3T3 cell used in the present investigation, do

not undergo the same orderly alteration in diverse aspects of metabolism, which permits the quiescence and non-proliferative survival of normal cells or those tumourigenic cells which retain the capability to enter the G_0 phase. Instead, they proliferate suicidally; and, during the death of the culture, cells are distributed in all phases of the cell cycle⁸. (*In vivo* tumourigenicity probably involves factors in addition to alteration of proliferative controls.) The SV3T3 cell protease activity was very similar to that of the 3T3 during logarithmic growth; however, in complete distinction from the untransformed cell, the SV3T3 cell activity remained constant even into the death phase of the culture (Fig. 2). The SV3T3 cells did not secrete an appreciable fraction of the total content of the activity into serum-free medium during a period of 10 h; therefore, extracellular secretion is not a major route of turnover of this enzyme in this cell type. Thus, this highly transformed cell, which has lost the ability to enter G_0 in response to starvation, has also completely lost the ability to elevate the enzymes responsible for the bulk of intracellular protein degradation. The observed deficiency in protease regulation could be secondary to loss of some central control mechanism which also governs other aspects of metabolism ('unitary lesion') or alternatively could be an independent event.

Fig. 1 Simultaneous variation in incorporation of thymidine per cell (a) and cathepsin D activity per cell (b) in BALB/c 3T3 cells compared with time in culture. 5×10^3 cells per 5-cm plate were seeded in Dulbecco-Vogt's modified Eagle's medium containing 10% foetal calf serum, and grown in a humidified incubator. At the time indicated by the arrow, the fluid of one group of plates was changed to fresh medium (■), whereas the other group was cultured in the original medium with no additions (●). At daily intervals, four plates of cells were counted with a Coulter counter (a, insert) and four plates were pulsed with ^3H -thymidine ($1 \mu\text{Ci ml}^{-1}$, $3 \mu\text{M}$, New England Nuclear, 6.7 Ci mmol^{-1}) for 2 h. Incorporated radioactivity per cell (a) was determined in washed 6% TCA precipitates (a). Cathepsin D activity (b) was determined by triplicate assay of the 0.1% Triton X-100 whole-cell homogenate pooled from four plates as described in Fig. 2. The decline in activity towards the initial value after fluid change was reproducible. Cell viability was 99% at day 10 as determined by Trypan dye exclusion. Increases in activity were somewhat greater when expressed as per unit of cell protein¹⁴.

Fig. 2 Cell growth (a) and cathepsin D proteolytic enzyme activity per cell (b) in 3T3 and SV3T3 mouse fibroblasts, compared with time after plating. Both 3T3 and SV3T3 cells were seeded at 10^4 cells per 5-cm plate in the same batch of Dulbecco-Vogt's modified Eagle's medium containing 10% foetal calf serum, and grown without changing the medium. In these conditions the 3T3 cell populations (●) ceased proliferation and entered the G_0 phase of the cell cycle at 6–8 d, whereas the SV3T3 cells (■) continued to divide into the death phase (a). At daily intervals, three plates of cells were rinsed three times with phosphate-buffered saline and collected by scraping in 1 ml 0.1% Triton X-100. Three parallel cultures were counted with a Coulter counter. The cells were homogenised by passage through a fine gauge needle 10 times, and cathepsin D activity was determined in the whole-cell homogenate at pH 2.8 in 0.2 M citrate-phosphate buffer by TCA solubilisation of ^3H -haemoglobin¹⁵. A unit of enzyme activity is equivalent to $1 \mu\text{g}$ haemoglobin hydrolysed to 6% TCA soluble form per 10^6 cells per hour. At 10 d the viability of the 3T3 cells was greater than 99%. The slight decrease in SV3T3 activity per cell is due to the presence of 5–7% dead cells adhering to the monolayer, and when corrected accordingly, yields a constant value. Cathepsin D activity increased 12–15-fold in primary cultures of BALB/c embryonic fibroblasts and in Swiss 3T3 cells similar to that shown above for BALB/c 3T3 cells (b, ●), but remained constant in the BALB/c SV3T3 cell (b, ■) and Swiss SV3T3 cell. Culture in 0.2% serum also caused no elevation of cathepsin D activity in the SV3T3 cell (data not shown).

The profile of pH against protease activity which contains several proteases in addition to cathepsin D, seemed to be identical in logarithmically growing 3T3 and SV3T3 cells (data not shown). Furthermore, the entire pH against activity profile in 3T3 cells increased in a precisely constant proportion, indicating a regulatory alteration common to at least several acid proteases.

As observed in tissue culture, loss of mitotic control is not an all-or-none phenomenon, and diverse tumourigenic cell lines retain varying extents of the properties usually considered indicative of normal cells. For example, the HTC hepatoma cell under extreme nutritional deprivation exhibits both a G_0 arrest⁹ and an elevation in protein degradation¹⁰, whereas the SV3T3 cell used in these investigations undergoes neither³. Therefore, the regulation of lysosomal proteases was investigated in a benzo(a)pyrene-transformed cell line (BP3T3) which enters $G_{0,1}$ only under extreme serum deprivation^{11,12}. Accordingly it was found that these cells exhibited an intermediate degree of loss of protease control.

The quantitative relationship between alterations in cell content of acid proteases and corresponding alterations in the actual rate of protein degradation is currently unknown. An important precaution in the interpretation of the present data is the fact that control over intracellular protein degradation probably involves several factors in addition to the cell content of lysosomal proteases^{2,13}. Nevertheless, in conjunction with supportive studies of protein degradation, the pronounced elevation of lysosomal protease activities in untransformed cells on quiescence and starvation, and

regulatory deficiency of proteases in transformed cells, imply an involvement of these enzymes in the events of normal and altered proliferative control and altered proliferative control.

Effect of hormones on herpes simplex virus type-2-induced transformation

GLUCOCORTICOID hormones enhance *in vitro* infections with murine leukaemia virus¹ and mouse mammary tumour virus². The yield of certain strains of herpes simplex virus type 2 (HSV-2) in certain cell types also increases in the presence of glucocorticoid hormones³. But in one limited study no significant differences were observed in the frequency of precancerous and cancerous lesions of the cervix in mice treated with oestrogens and HSV-2 or oestrogen alone⁴. Because there is epidemiological evidence that HSV-2 may be oncogenic in humans⁵, and experimental evidence that inactivated HSV-2 can produce malignant transformation of hamster embryo fibroblast cells *in vitro*^{6,7}, we have studied the effect of different hormones on HSV-2-induced transformation. We have used a rapid quantitative assay for transformation by HSV-2, using a thymidine kinase (TK) selection procedure described elsewhere (ref. 8 and unpublished work with N. Turner). These transformed cells have been shown to contain HSV-specific antigens as determined by indirect immunofluorescence, but do not yield infectious HSV. Our results indicate that 10^{-6} M cortisol and 10^{-8} M oestradiol inhibit HSV-2-induced transformation, and that dexamethasone has very little effect on the incidence of transformation.

A TK⁻ mouse cell line (designated N c1A c110) was obtained from Dr R. Goldberg of the National Institutes of Health and grown in 100-mm Petri dishes in Dulbecco modified Eagle medium supplemented with 10% foetal calf serum (FCS). HSV-2 strain 333 grown in Vero cells was used.

In transformation experiments, virus was ultraviolet-irradiated at $46 \text{ erg s}^{-1} \text{ mm}^{-2}$ and was mixed with trypsinised N c1A c110 cells (6×10^4 cells) at an unirradiated input multiplicity of 2.0 in 2 ml of Dulbecco medium. After adsorption for 1.5 h at room temperature, 15 ml of Dulbecco modified Eagle medium containing 0.16 mM thymidine, 0.05 mM adenosine, 0.1 mM glycine and 0.05 mM guanosine (TAGG medium) was added and the plates were incubated at 37 °C. After 72 h, the medium was removed and 15 ml of MTAGG medium (TAGG medium supplemented with 0.0006 mM methotrexate)⁹ was added. The cells were refed with MTAGG medium 5 d after the original feeding and weekly thereafter. Three weeks after infection, cultures

Table 1 Effect of hormones on HSV-2-induced transformation

Hormone treatment	Average no. of clones per plate	% of control
Untreated control	52	100
Cortisol, 10^{-6} M	10	20
Cortisol, 10^{-8} M	11	20
Cortisol, 10^{-7} M	15	22
Oestradiol-17 β , 10^{-8} M	8	15
Oestradiol-17 β , 10^{-6} M	40	80
Oestradiol-17 β , 10^{-7} M	45	90
Dexamethasone, 10^{-6} M	42	80
Dexamethasone, 10^{-8} M	52	100
Dexamethasone, 10^{-7} M	45	90

HSV-2-induced transformation was measured as described in the text. Hormones were added 4 h after the addition of irradiated virus and remained present for 21 d. Number of clones per plate is average of 4 replicate plates. Mock-infected N c1A c110 cells did not develop clones.

were fixed with 5% formalin and stained with a 1% aqueous solution of crystal violet. Hormones (Sigma) were dissolved in absolute alcohol and added to the medium in appropriate final concentration.

The HSV-2-induced transformation was carried out in the presence of cortisol, oestradiol-17 β or dexamethasone. Table 1 shows a fivefold decrease in the number of transformed clones that developed in the presence of cortisol (10^{-6} to 10^{-7} M). Oestradiol considerably inhibited the number of transformed clones at a concentration of 10^{-8} M, but had no effect at concentrations of 10^{-6} M or lower. In contrast, dexamethasone had very little effect on the number of transformed clones at all concentrations (10^{-8} to 10^{-7} M) examined. Pretreatment of cells with hormones before infection and continuation of hormone treatment after infection (data not shown) did not alter the results described in Table 1.

To determine whether the observed inhibitory effect of cortisol and oestradiol is due to the toxic effect on host cells, N c1A c110 cells were treated with cortisol and oestradiol. After incubation at 37 °C for 48 h, cell numbers and DNA and protein synthesis were measured and compared with untreated controls. Because these cells are deficient in TK, DNA synthesis was measured by determining the incorporation of ³H-hypoxanthine into alkaline-trichloroacetic acid (TCA)-insoluble material. Table 2 shows that cell numbers, DNA and protein synthesis were not affected by treatment with cortisol or oestradiol at a concentration which inhibited HSV-2-induced transformation. This is further supported by the observation that pretreatment of cells with hormones before the addition of irradiated virus had no inhibitory effect on HSV-2-induced transformation (Table 3).

To determine whether the presence of hormones is

Table 2 Effect of hormones on cell growth and DNA and protein synthesis

	Cell no.* per plate ($\times 10^4$)	DNA synthesis† ³ H-hypoxanthine incorporated (c.p.m.)	Protein synthesis† ³⁵ S-methionine incorporated (c.p.m.)
Untreated control	4.80	23,840	59,451
Cortisol, 10^{-6} M	4.89	21,486	61,118
Oestradiol, 10^{-8} M	4.35	22,576	62,198

*Hormones were added 6 h after seeding the N c1A c110 cells into 60-mm Petri dishes. Two days later, both treated and untreated cultures were trypsinised and counted. Number represents average of two replicate plates.

†Hormones were added as described above. One day later, ³H-hypoxanthine and ³⁵S-methionine were added to both untreated and hormone-treated cells to a final concentration of $1 \mu\text{Ci ml}^{-1}$ and $2 \mu\text{Ci ml}^{-1}$, respectively. After incubation for 48 h at 37 °C, ³⁵S-methionine-labelled cells were lysed with 2% sodium dodecyl sulphate and TCA-precipitable radioactivity was determined. Hypoxanthine-labelled cells were lysed by 0.4% Triton X-100 and digested with 0.3 N KOH at 37 °C overnight, after which TCA-precipitable radioactivity was determined.

necessary throughout the 21 d of incubation, cortisol (10^{-6} M) was kept in the medium for various times and its effect on the number of transformed clones was examined. Data indicate that the presence of cortisol was necessary only for the first 2 d after infection to exhibit inhibitory effect, although inhibitory effect is maximum between 2 and 4 d after addition of virus.

We have examined the possibility that the observed inhibition of transformation is somehow related to a more generalised inhibition of herpes virus development in productive infection. Table 4 indicates that cortisol (10^{-6} M) and oestradiol (10^{-8} M) had no effect on the formulation of herpes virus progeny or on viral DNA synthesis.

Our results demonstrate that HSV-2-induced transformation is inhibited in the presence of cortisol (10^{-6} to 10^{-7} M) and oestradiol (10^{-8} M). In contrast, dexamethasone has very little effect on HSV-2-induced transformation. We do not know why dexamethasone and cortisol, both being glucocorticoid hormones, have different effects on transformation. The difference could be due to the differences in cell receptor for the natural (for example, cortisol) and synthetic (for example, dexamethasone) hormone.

Table 3 Effect of cortisol on HSV-2-induced transformation at various times after infection

Cortisol present (d)	No. of transformed clones per plate
None	55
-2 to 0	50
0 to 2	18
0 to 4	11
0 to 10	10
0 to 21	11
10 to 21	56

Transformation was carried out as described in the legend to Table 1. The interval in which cortisol was present is indicated, zero being the day of virus addition. Twenty-one days after infection, transformed clones were stained and counted. Number of clones per plate is the average of four replicate plates.

Hormones were added 3-4 h after the virus in the transformation assay. We therefore concluded that the inhibition of transformation by hormones is probably not due to the failure of adsorption, penetration or uncoating of infecting virus particles. This was further supported by the fact that the inhibition of transformation was still observed when hormones were added 6-7 h after addition of virus (data not shown). We do not know whether parental viral DNA undergoes replication in the transformation process. Even if the viral DNA is replicated during transformation, this replication probably would not be inhibited by cortisol or oestradiol, because these hormones have no inhibitory effect on viral DNA synthesis in productive infection (Table 4). Because the addition of cortisol at late infection (10 d after infection) did not inhibit transformation (Table 3), it may be concluded that hormones probably do not act at the level of transcription or translation of the virus gene. One possible explanation is that hormones inhibit the integration of HSV-2 DNA into the cellular genome. In the absence of permanent association of viral DNA with the cellular genome, the genetic information for TK is not transferred to the daughter cells, and therefore the formation of transformed clones is inhibited. The mechanism by which hormones might inhibit integration of viral genes into the cellular genome is unknown. This may inhibit the steps involved in integration, for example, specific cleavage of the cellular DNA, circularisation of virus DNA, or joining of virus DNA with cellular DNA. The role of hormones in virus integration has not been reported, but this study may suggest a potential use of hormones to study this

Table 4 Effect of hormones on the synthesis of virus progeny and virus DNA in HSV-2-infected N c1A c110 cells

	Virus yield* (PFU per plate)	DNA synthesis† ³ H-thymidine incorporated (c.p.m.)
Untreated control	4.5×10^6	4.2×10^4
Cortisol 10^{-6} M	4.2×10^6	9.0×10^5
Oestradiol 10^{-8} M	4.3×10^6	3.8×10^4

*Confluent monolayers of N c1A c110 cells were infected with HSV-2 strain 333 at an input multiplicity of 1. After adsorption of virus for 1 h at 37 °C, Dulbecco's modified Eagle medium containing 5% FCS was added. At 24 h after infection, cells were scraped into the medium and the mixture was frozen and thawed three times. After centrifugation at 1,000 r.p.m. for 5 min, the supernatant was assayed for viral progeny in rabbit kidney cells by plaque assay. Numbers represent average of two plates.

†Confluent cells were infected with HSV-2 at an input multiplicity of 5 as described above. At 7 h after infection, ³H-thymidine was added to a concentration of 5 μ Ci ml⁻¹. After 24 h of infection, labelling medium was removed, cells were lysed by 2% sodium dodecyl sulphate and TCA-precipitable radioactivity was determined. Because the CsCl density gradient analysis of labelled DNA synthesised after 7 h of infection is mostly virus specific (our unpublished results), incorporated radioactivity represents virus-specific DNA.

phenomenon. We do not have any direct information about the presence of hormone receptors in N c1A c110 cells, but in conjunction with the accepted mode of action of steroid hormones, we can assume that in this case hormones are also acting through specific cell receptors. There are several possible reasons why we did not see any significant effect of hormones in the productive system. The frequency of integration during the productive infection is presumably very low and any effects would be minimal. Also, productive infection with HSV may change the receptor level in the cells, thereby rendering infected cells insensitive to hormones.

This study was supported by a contract within the Virus Cancer Program of the NCI and by a grant from NCI. We thank Drs R. L. Miller and M. K. Howett for helpful discussions and Dr C. Gupta for hormones.

Cytoskeletal regulation of concanavalin A capping in pulmonary alveolar macrophages

CONCAVALIN A (con A) capping occurs in polymorphonuclear leukocytes (PMN) and is thought to be dependent on disruption of microtubules with subsequent lateral movement of lectin receptors to a polar region in the plasma membrane¹. Capping in PMN is induced by colchicine but is blocked by cytochalasin B, an inhibitor of microfilament assembly². Based on these observations, a cytoskeletal system that effects transmembrane control of receptor mobility has been proposed. The microtubules system interacts directly or indirectly with membrane components to limit the

Fig. 1 Photomicrograph of alveolar macrophages showing diffuse fluorescence (A) and polarised fluorescence pattern (cap) (B). Small arrowheads show cell outline, large arrowhead points to fluorescent uropod cap. ($\times 400$.)

mobility of surface receptors while the contractile system of microfilaments may enhance the movement of these receptors into caps³. Here we report that capping also occurs in guinea pig alveolar macrophages (AM), and that the factors which regulate AM surface receptor movement differ dramatically from those in PMN. AM are capped by cytochalasin B alone, which is contrary to the experience with the PMN. AM capping is dependent on oxidative phosphorylation and the cap is associated with formation of a striking uropod (Fig. 1).

Guinea pig AM were obtained using the method of Rister and Baehner⁴, in Krebs-Ringer-phosphate (KRP) buffer with 5 mM glucose. Fluorescein-conjugated con A (FITC-con A, Yeda) was suspended in normal saline. AM were incubated for 2 min at 37 °C; after addition of appropriate drugs (Table 1) for 15 min, AM were labelled with FITC-con A for 5 min at 37 °C, then fixed for 10 min at 28 °C with formaldehyde and centrifuged for 10 min. Slides were prepared and capped cells counted.

Table 1 shows the response of AM to various drugs. Colchicine-induced capping was not inhibited by pretreatment of AM with cytochalasin B ($10 \mu\text{g ml}^{-1}$). Cytochalasin B treatment ($1-20 \mu\text{g ml}^{-1}$) induced an equivalent degree of capping as noted with colchicine. Dimethyl sulphoxide (DMSO), the solvent for cytochalasin B had no effect on

Table 1 Effect of various additions on concanavalin A capping in pulmonary alveolar macrophages

Addition	% Capped
None (control)	31.6 ± 8.5
Colchicine (10^{-5} M)	63.0 ± 7.7
Colchicine (10^{-5} M) + cytochalasin B ($10 \mu\text{g ml}^{-1}$)	78.0 ± 0.9
Cytochalasin B	
1 $\mu\text{g ml}^{-1}$	70.5 ± 4.3
5 $\mu\text{g ml}^{-1}$	78.6 ± 7.3
20 $\mu\text{g ml}^{-1}$	73.2 ± 14.6
DMSO 300 $\mu\text{g ml}^{-1}$	18.2 ± 6.3
Colchicine (10^{-5} M) at 4 °C	0 0
then warmed to 37 °C	66, 65
Cytochalasin B ($10 \mu\text{g ml}^{-1}$) at 4 °C	0 0
then warmed to 37 °C	70, 73
Potassium cyanide (1 mM)	0 0
2-Deoxyglucose (1 mM)	31, 34

Alveolar macrophages (2×10^6 cells) were incubated at 37 °C in a shaking water bath in KRP buffer, 3 ml total volume, containing 5 mM glucose with drugs indicated. After 15 min cells were stained with FITC-con A ($50 \mu\text{g}$) at 37 °C for 5 min, then fixed with 2% formaldehyde for 10 min at 28 °C. Cells were then washed once and centrifuged and slides made from the cell button. Results were obtained by examining 200 cells per slide at random with a Zeiss fluorescence microscope (FITC-exciter filter, 530 barrier filter) and classifying each cell as capped or not capped. Values represent means $\pm$ s.d.

capping. Capping did not occur at 4 °C although warming the AM suspension to 37 °C for 15 min produced maximal capping. AM treated for 45 min with potassium cyanide did not cap, whereas incubation with 2-deoxyglucose, an inhibitor of anaerobic glycolysis⁵ had little effect on capping indicating a dependence on energy derived from oxidative phosphorylation.

Transmission electron microscope studies were carried out to determine the intracellular location of microfilaments and microtubules in capped cells (Fig. 2). In cells treated with colchicine (Fig. 2a), few microtubules were visualised and the cap contained an abundance of microfilaments. In

Fig. 2 Transmittance electron micrograph of alveolar macrophages *a*, capped after treatment with colchicine in which microtubules are not apparent, and *b*, after cytochalasin B. A, Outlines the region of cell cap; B, 100 Å filaments; C, microfilament rich region in cap. ($\times 7,000$.)

cells treated with cytochalasin B (Fig. 2b), the caps were surrounded by typical cytochalasin B polarised blebs⁶, but the caps in these cells were also rich in microfilaments.

This study shows that con A capping in the AM can be induced by inhibitors of both microtubule and microfilament assembly. Thus in AM, some microfilaments and microtubules do not seem to have opposing roles in controlling membrane fluidity, as some recent theories propose for other cell types³. Instead, it seems that in the AM, redistribution of lectin receptors, as occurs in capping, could be dependent on a set of microfilaments that are not sensitive to cytochalasin B. Other studies have proposed such a set of microfilaments in the AM (ref. 7). The receptor mobility in the AM may be limited by both the microtubules, as in other cell types, and a subset of microfilaments sensitive to cytochalasin B.

α -Fetoprotein induces suppressor T cells *in vitro*

THE ability of α -fetoprotein (AFP) of mouse or human origin to suppress certain T cell-dependent immune reactions *in vitro* is well documented¹⁻⁴. These findings on a tumour-associated embryonic substance⁵ have potentially important implications as to our understanding of the maternal-foetal immunological relationship⁶, the development of immune capabilities in the foetus and newborn⁷, and of certain diseases⁸ where immunological hyporeactivity and elevations in AFP often occur concomitantly. The mechanism(s) through which AFP is exerting its immunoregulatory influence is largely unknown; however, previous studies¹ have shown that AFP must be added at the initiation of antigen-stimulated spleen cell cultures for maximal inhibition of primary antibody synthesis to occur.

Continued presence of AFP in the cultures for 8-12 h was sufficient to maintain suppression in an AFP-free environment for at least 5 d *in vitro*¹ and 10 d *in vivo* using adoptive transfer experiments (unpublished). These observations suggested that AFP may inhibit immune responses indirectly by activating regulatory suppressor cells. Here we report that AFP does indeed induce the formation of highly efficient suppressor T cells with capacity to inhibit helper T cells, but with no effect on B cells responding to thymus independent antigens.

Mouse amniotic fluid (MAF) was collected from pregnant outbred Swiss mice (Anticimex, Stockholm) between day 14 and day 16 of gestation. AFP was isolated from MAF by a two-step procedure of affinity chromatography and preparative polyacrylamide gel electrophoresis as described before¹. Purity was checked by gel electrophoresis and immunological tests. In initial experiments normal adult C57BL/6 or BALB/c spleen cells were cultured in Marbrook chambers⁹ with purified AFP, MAF or normal mouse serum (NMS) at equivalent final concentrations in the cultures of 200 μ g ml⁻¹ for 4 d. There were no significant differences in the yields of viable lymphocytes from cultures containing AFP, MAF, and NMS. The precultured cells were then washed, and 10⁶ cells were added to 20 $\times$ 10⁶ fresh normal spleen cells in new Marbrook cultures along with an optimal immunising dose of sheep red blood cells (SRBC). After 4 d in culture the cells were harvested and assayed for primary plaque-forming-cells (PFC) to SRBC. The results of three such experiments are summarised in Table 1. In all experiments the addition of spleen cells precultured in MAF or MAF-derived AFP to assay cultures caused significant suppression of the PFC response to SRBC.

The time-course of development of suppressing ability was determined by assaying for suppressor cell activity after various preculture times ranging from 6 to 96 h. Because of the limited amount of purified AFP available, these and subsequent experiments to be described in this report were performed with MAF. It is justified in this system to attribute the resulting effect to AFP since the previous experiments (Table 1) showed that equivalent suppressor cell activity is obtained by preculturing with AFP and MAF. It has also been clearly demonstrated¹ that the factor in MAF responsible for its suppressive effect on T cell-dependent immune responses is AFP. Although some suppression was evident after 2 d of preculture, 3-4 d were required for maximum development of suppressor cell activity (Table 2). This suggests that AFP is actively generating suppressor cells through a process involving cell proliferation and/or differentiation. In line with this are findings in another test system that AFP under certain culture conditions will induce proliferation of normal mouse T lymphocytes (A. B. Peck, R. A. M. and H. W., in preparation).

Table 1 Suppression of the primary PFC response to SRBC by spleen cells precultured in AFP

Preculture* Cells precultured in:	No. of precultured cells added	Assay culture† γ M PFC per culture (% suppression)		
		Experiment 1	2	3
NMS	10 ⁶	1,800	1,640	900
AFP	10 ⁶	2,340 (0)	2,000 (0)	1,116 (0)
MAF	10 ⁶	850 (53)	510 (69)	370 (59)
		1,000 (46)	420 (74)	573 (36)

*20 $\times$ 10⁶ normal mouse spleen cells were precultured with 200 μ g ml⁻¹ NMS (normal mouse serum), AFP (α -fetoprotein) or MAF (mouse amniotic fluid) in Marbrook chambers⁹ using RPMI 1640 medium supplemented with 10% foetal calf serum, 10 mM HEPES and 5 $\times$ 10⁻⁵ M 2-mercaptoethanol. After 4 d of incubation at 37 °C in 5% CO₂ humid atmosphere, the cells were collected and viable cells were counted by a dye exclusion method.

†10⁶ Viable lymphocytes precultured as indicated above were added to assay cultures of 20 $\times$ 10⁶ fresh normal spleen cells stimulated with 3 $\times$ 10⁶ SRBC in Marbrook chambers⁹. One set of control cultures consisted of fresh spleen cells and antigen without added precultured cells. Direct anti-SRBC PFC were assayed after 4 d in culture². The data from three representative experiments are expressed as arithmetic means of three cultures per group.

Table 2 Time course of development of suppressor cells *in vitro*

Preculture*		Assay culture†	
Cells precultured in:	Duration of preculture (h)	γ M PFC per culture	% Suppression
NMS	6	935 $\pm$ 45	6
MAF		1,019 $\pm$ 214	0
NMS		1,171 $\pm$ 158	0
MAF	12	1,197 $\pm$ 145	0
NMS		1,092 $\pm$ 73	0
MAF		1,095 $\pm$ 125	0
NMS	24	887 $\pm$ 174	11
MAF		638 $\pm$ 89	36
NMS		918 $\pm$ 56	8
MAF	48	560 $\pm$ 65	44
NMS		1,000 $\pm$ 91	0
MAF		372 $\pm$ 41	63

*Preculture conditions were as described in the legend to Table 1. The duration of the precultures varied from 6–96 h as indicated.

† 10^6 Viable lymphocytes from preculture were added to assay culture stimulated with SRBC as described in Table 1. Control cultures (cells precultured in NMS) in the experimental group receiving 96 h precultured cells were arbitrarily adjusted to 1,000 PFC per culture. All other values were normalised to these control cultures. Each value represents the mean and s.e.m. of triplicate cultures.

Results presented in Table 3 suggest that the suppressor cell activity induced by AFP is mediated by T lymphocytes. Here the degree of suppressor cell activity generated in precultures of unfractionated spleen cells was compared with that generated by splenic T cells isolated by affinity fractionation on glass bead columns¹⁰. There was a significant enrichment of suppressor activity in precultures of purified T cells, whereas suppressor activity was absent in precultures of spleen cells from nude (*nu/nu*) mice with a BALB/c background, but present in precultures of normal BALB/c spleen cells (Table 3).

A dilution analysis of the suppressor T-cell activity was then performed by adding graded numbers of precultured cells to assay cultures of 20×10^6 normal spleen cells which were then challenged with SRBC or with the thymus independent antigen DNP₃₂-Ficoll¹¹ (DNP, 2,4-dinitrophenyl). and assayed for PFC to SRBC or TNP (2,4,6-trinitrophenyl). A linear dilution effect of AFP-induced suppressor cell activity on SRBC PFC responses was obtained within the range of 10^7 – 10^4 added cells as shown in Fig. 1b. As few as 10^4 suppressor cells (0.05% of total cell population) markedly inhibited T cell-dependent anti-SRBC responses. There was, however, no effect of suppressor cells on the antibody response to DNP₃₂-Ficoll (Fig. 1a). A similar pattern of suppression of T cell-dependent antibody responses

Fig. 1 Effects of various numbers of precultured cells on the primary *in vitro* antibody response to $10 \mu\text{g ml}^{-1}$ DNP₃₂-Ficoll (a), and 3×10^6 SRBC (b). The abscissa denotes the number of viable precultured cells added to standard assay cultures. Grey bars refer to antigen-stimulated control cultures without added precultured cells. Open bars refer to cells precultured in NMS and black shaded bars refer to cells precultured in MAF. The thymus-independent PFC response to DNP₃₂-Ficoll¹¹ was assayed against TNP-SRBC².

to DNP-KLH, and a lack of inhibition of T cell-independent antibody responses to DNP-POL has been recorded in several, additional experiments.

Thus our results strongly suggest that one mode of immunoregulatory action by AFP is the generation of suppressor T cells which control the level of responsiveness to T cell-dependent antigens. This is quite in agreement with the findings that in newborn mice with high intrinsic concentrations of AFP there exist efficient numbers of sup-

Table 3 Evidence that T cells mediate suppressor activity *in vitro*

*Normal spleen cells, Ig-anti-Ig column purified splenic T cells¹⁰, or spleen cells from thymus-deficient (*nu/nu*) mice were precultured in NMS or MAF for 4 d as described in Table 1.

†The SRBC PFC responses in control cultures of fresh normal spleen cells without added precultured cells were adjusted to 1,000 and experimental values were normalised as described in Table 2.

pressor T lymphocytes^{12,13}. Also, it is known that thymus-derived lymphocytes from newborn humans can function as suppressor cells with regard to the proliferative capacities of the lymphocytes from their mothers (ref. 14 and L. B. Olding, R.A.M. and H.W., in preparation). We therefore suggest that AFP serves as an agent to protect the mammalian foetus from graft-versus-host and host-versus-graft reactions through the selective induction of suppressor T cells. The exact mechanism(s) through which AFP is exerting this activity is now a major target of analysis.

Unmasking of thromboxane A₂ synthesis by ureteral obstruction in the rabbit kidney

THE rabbit kidney has a high capacity for prostaglandin biosynthesis. The major renal prostaglandin released in response to various stimuli is PGE₂, a vasodepressor prostaglandin¹ thought to have a role in the regulation of intrarenal blood flow². Although renal prostaglandin synthesis may initiate a reduction in vascular resistance of the kidney in response to reduced perfusion pressure, it has not been possible to establish a functional role for renal prostaglandins as mediators of increased vascular resistance evoked by augmented renal perfusion pressure. An increase in renal resistance, if related to changes in the rate of synthesis of endogenous substances, implies the biosynthesis of a vasoconstrictor or suppression of the basal production of a vasodepressor material. Unilateral ureteral obstruction (model of hydronephrosis) in the dog, rat and rabbit is initially associated with a decrease in renal resistance which is followed by a fall in GFR and renal blood flow^{3,4} by 24 h post-occlusion. The initial renal vasodilator phase may be associated with enhanced renal basal PGE₂ synthesis and markedly facilitated PG release in response to hormone stimulation⁵. Here we report the observation that the ureter-obstructed kidney may be producing a natural vasoconstrictor material.

New Zealand male white rabbits were anaesthetised with pentobarbital and the left ureter was ligated⁶. Three days later the rabbits were anaesthetised and both kidneys (ipsilateral ureter obstructed and contralateral untouched kidney) were removed and perfused (15 ml min⁻¹) with Krebs-Henseleit buffer at 37 °C as previously described⁵. The venous effluent was allowed to flow over a series of biological assay organs (rabbit aorta, chick rectum, rat stomach) which were selected to

detect the presence of PGE, PG-endoperoxides and thromboxane-like substances (details Fig. 1 legend).

The isolated perfused rabbit kidney, with the ligated ureter, released into the venous effluent a substance which contracted the rabbit aorta following the administration of a dose of bradykinin (100 ng) (Fig. 1). The contralateral kidney did not release the vasoconstrictor into the effluent even with very high doses of bradykinin (2,000 ng). Alterations in bradykinin metabolism were not enough to explain differences in release from hydronephrotic and contralateral kidney⁶. Indomethacin, a known inhibitor of the cyclo-oxygenase⁸, abolished the generation of the aortic constrictor by the ureter obstructed kidney in response to bradykinin. The PG products of cyclo-oxygenase known to constrict the rabbit aorta are the endoperoxides, PGH₂ and PGG₂ (half life 6–7 min at 37 °C) and thromboxane A₂ (half life 30 s)^{9,10}. The endoperoxides, which are moderately potent aorta vasoconstrictors, are rapidly converted to the classical prostaglandins (PGE₂, PGD₂) by enzymic and non-enzymic breakdown. The enzyme thromboxane synthetase converts the endoperoxide PGH₂ to the potent constrictor thromboxane A₂ and has been demonstrated in platelets⁹, spleen¹⁰ and lung¹¹. Thromboxane synthetase has not been described in the kidney.

To ascertain which of these two prostaglandin constrictors was being produced in the hydronephrotic kidney, the half-time of disappearance of the constrictor substance from the aqueous media was estimated by bioassay. The venous effluent released in response to hormone stimulation was collected, reoxygenated and reperfused over a second aortic strip after a delay of 1.5 min. The original effluent contains both PGE₂ (that is contraction of chick rectum and rat stomach) which is stable in aqueous solution at 37 °C and the rabbit aorta constricting substance (Fig. 2). Following the 1.5 min delay the PGE₂ activity was still present but the constrictor substance had completely disappeared. PGH₂ injected directly over the strips and subjected to the same delay of 1.5 min still produced contraction of the aorta. This instability in aqueous solution suggested that the constrictor was the more labile thromboxane A₂ and not the endoperoxide PGH₂. The renal release of rabbit aorta constrictor activity was dose dependent and was also released from the hydronephrotic kidney following stimula-

Fig. 1 The release of a rabbit aorta contracting substance from a ureter obstructed kidney by bradykinin. The venous effluent from the perfused rabbit kidney is allowed to superfuse a rabbit aortic strip and a rat fundal strip. Sensitivity and selectivity of the assay tissues were increased by an infusion of antagonists⁶ to histamine, acetylcholine, catecholamines and 5-hydroxytryptamine as well as indomethacin (1 µg ml⁻¹) to prevent endogenous synthesis of prostaglandins by the tissues⁷. PP, renal artery perfusion pressure; RSS, rat (fundic) stomach strip; RA, rabbit aortic strip; DIR, injection directly over strips; TK, through the kidney; BK, bradykinin; PGH₂, endoperoxide; HNK, hydronephrotic or ureter obstructed kidney; and CLK, contralateral or untouched kidney (n = 10).

tion with angiotensin II 50 ng but not from contralateral kidney with doses up to 1,000 ng (data not shown).

Microsomal fractions from kidney homogenates were prepared for the radiochemical verification of thromboxane synthesis in the hydronephrotic kidney. The kidneys were minced and homogenised (Polytron) in 3 volumes of 100 mM phosphate buffer pH 7.5. The homogenate was centrifuged (8,000g, 15 min) and the supernatant was centrifuged at 100,000g for 60 min. The pellet was resuspended in 100 mM phosphate buffer pH 7.5 in a volume equal to one fourth original wet weight of the tissue. The kidney microsomes (2 mg protein per ml) were incubated with ^{14}C -arachidonic acid in the presence of 1.2 mM L-adrenaline¹³ for 30 min at 37 °C and the volume of the reaction mixture was 1 ml. The reaction was acidified to pH 3.5 with citric acid and extracted twice with 2 volumes of ethyl acetate. The ethyl acetate phase was evaporated to dryness and reconstituted in chloroform-methanol (2:1) and applied to silica gel thin layer plates in a solvent system of benzene-dioxane-acetic acid (60:30:3). The radiochromatogram obtained from the incubation of kidney microsomes and ^{14}C -AA shows radioactive peaks corresponding to PGE_2 , $\text{PGF}_{2\alpha}$, PGD_2 and TXB_2 (thromboxane B_2). Similarly, using another solvent system (chloroform-methanol-acetic acid-water, 90:8:1:0.8) a thromboxane B_2 peak was detected between $\text{PGF}_{2\alpha}$ and PGE_2 . Thus, using two different solvent systems it is possible to demonstrate an arachidonate product which has chromatographic mobility similar to that of thromboxane B_2 . More specific proof of synthesis was obtained by performing the enzymic incubation in the presence of imidazole, a specific antagonist of thromboxane synthetase¹⁴. The thromboxane B_2 peaks were abolished when the renal microsomes were reacted with arachidonate in the presence of 5 mM imidazole (Fig. 3). Similar results, that is, thromboxane B_2 formation which was inhibitable by imidazole, were obtained using ^{14}C -PGH₂ as substrate (instead of ^{14}C -arachidonic acid) with kidney microsomes at 0 °C for 20 min. Only the ureter obstructed kidney seems to possess thromboxane synthetase activity since identical experiments carried out with microsomes prepared from the contralateral unobstructed kidney did not show evidence of a thromboxane B_2 peak on radiochromatograms. These experiments indicate that the microsomal preparation from rabbit kidneys after 3 d of ureteral occlusion can synthesise thromboxane A_2 from arachidonate or the endoperoxide PGH₂. The ureter-obstructed kidney converted 2.5–3% of the total arachidonate radioactivity to

Fig. 2 Bioassay of rabbit aorta constricting substance (RCS). a, Response of the assay strips, rat stomach strip (RSS) (top) and rabbit aortic strip (RA) (lower trace) to PGE_2 160 ng directly over the strips (DIR) and endoperoxide generated from sheep seminal vesicles (SSV) and arachidonate (AA)¹⁸. b, Contractions of RSS and RA to 200 ng bradykinin (BK) through the kidney (TK). This effluent was collected, reoxygenated and reperfused over a second aortic strip, shown in (c). c, Trace showing complete loss of contractile activity on rabbit aorta after 1.5 min but persistence of PGE_2 activity as indicated by contraction of RSS ($n = 10$).

Fig. 3 Thin-layer radiochromatograms of the acid-lipid extract obtained from rabbit kidney microsomes and ^{14}C -arachidonic acid. The upper scan shows the peak of radioactivity between PGE_2 and PGD_2 corresponding to TXB_2 . The lower scan shows loss of this peak when incubations were carried out in the presence of imidazole 5 mM. The mobility of the cold standards in the solvent system of benzene-dioxane-acetic acid (60:30:3) are indicated on the scans. Standards used were $\text{PGF}_{2\alpha}$ ($\text{F}_{2\alpha}$), (E_2) PGE_2 , PGD_2 (D_2), PGA_2 (A_2) and arachidonic acid (AA) (all gifts from Upjohn). TB_2 , thromboxane B_2 ; APM, aspirin treated platelet microsomes ($n = 5$).

^{14}C TXB_2 . The percentage ^{14}C radioactivity converted to PGE_2 , $\text{PGF}_{2\alpha}$ and PGD_2 were 15%, 10% and 5% respectively. Assuming lower rates of conversion for the contralateral kidney, the amount of thromboxane B_2 formed may be below the lower limit of our discrimination.

The unmasking of thromboxane synthetase activity in the experimental model of ureteral obstruction suggests that the biosynthesis of thromboxane A_2 may be important to the alterations in renal vascular resistance and regional blood flow. The potential role of thromboxane A_2 in ureteral obstruction, if it is produced in other species, may be in the alterations in regional blood flow to non-functioning areas of the kidney or decreases in total renal blood flow to a non-functioning kidney in a pathological situation. The capacity to unmask renal thromboxane synthetase activity may give new insight into some old problems.

Is yawning a cholinergic response?

BARBIZET¹ was perhaps right in suggesting that the commonplace, ubiquitous and apparently non-significant nature of the act of yawning, might have contributed to the relative lack of attention given by physiologists to this behavioural phenomenon. The physiological significance of yawning and the nervous mechanisms triggering and coordinating its various components remain unclear^{1,2}. Frequent yawning has been mentioned as a symptom in some diseases of the central nervous system, particularly in cases of frontal tumours and encephalitis^{3,4}. A stretching and yawning syndrome has been observed in cats, dogs and monkeys after intracisternal or intraventricular injections of adrenocorticotrophic and melanotrophic hormones, or synthetic polypeptides with ACTH and/or MSH activities^{5,6}, but the relation of these observations to the basic mechanism of yawning has not been studied. During experiments designed to explore cholinergic potentiation of D-amphetamine induced head-shaking in infant rats⁷, we have made some observations that indicate the involvement of a central cholinergic response in yawning.

Infant rats, from 6 h after birth up to 14 d old, were injected intraperitoneally (i.p.) with physostigmine salicylate (0.10 mg of the free base per kg body weight, dissolved in 0.9% NaCl to a total volume of 0.01 ml per g bodyweight). The rats began to yawn about 5 min after the injection. In the following 15 min the number of yawns reached an average of 10–12 during the first 10 d of life. Some animals yawned twice per minute, and others only a couple of times in 15 min. In rats aged under 10 d physostigmine induced yawning was practically universal. Between days 10 and 14 of life the frequency of yawning fell rather steeply, to a level of only 2 or 3 yawns per 15 min, with some animals showing no yawning response. At the 14th day yawning occurrence had decreased to 69% of the population. Each yawn was preceded by salivation, licking of the forepaws and cleaning movements of the snout, or 'gumming' or chewing movements, and sometimes by a sudden stretching of the forelimbs. The yawn itself was a slow wide opening of the mouth, with marked protrusion of the tongue, and lasted about 3–4 s (Fig. 1).

A dose-effect graph of physostigmine induced yawning in

Fig. 1 Physostigmine-induced yawning in a male rat (3 months old) injected with physostigmine at 0.10 mg per kg body weight.

Fig. 2 Physostigmine and pilocarpine induced yawning. Drug doses (free base) are indicated in each column (mg per kg body weight). Each group consisted of 12 nine-day-old rats. All values after drug injection are significantly different from the controls as follows: physostigmine, 0.05 mg, $P < 0.05$; 0.10 and 0.20 mg, $P < 0.001$; 0.30 mg, $P < 0.003$; pilocarpine, all doses tested, $P < 0.001$ (Mann-Whitney U test⁸).

9-d-old rats is shown in Fig. 2. That this particular action of the anticholinesterase drug is centrally mediated is strongly suggested by control experiments with neostigmine methylsulphate, which passes the blood-brain barrier with difficulty. When injected i.p., in a dose of 0.2 mg per kg, neostigmine induced only 1.6 yawns per 15 min (12 animals). Although this effect is significantly different from that observed in rats injected with saline ($P < 0.01$) it was only of the order of one-sixth of the effect obtained with physostigmine. With higher doses of neostigmine no yawning was observed. Pilocarpine hydrochloride, a cholinomimetic drug that passes readily into the brain, induced yawning up to the same level as physostigmine (Fig. 2).

Cholinomimetically induced yawning seems to be due to the stimulation of central 'muscarinic' receptors, because it is rapidly and completely blocked by scopolamine hydrobromide, at doses of 2.5 to 5 mg per kg (Fig. 3). That 'nicotinic' cholinergic receptors are not participating was demonstrated with nicotine administered by i.p. injection. Doses of nicotine (0.1 mg per kg) which induced clear central effects on head-shaking (unpublished observations) did not induce yawning.

We observed physostigmine induced yawning at a more or less stable level of 2–3 yawns per 15 min in rats from 14 to 90 d of age, but practically only in males. In a pool of 62 animals (31 females and 31 males, 14 to 54 d old) from the same litters, males performed an average of 3.1 yawns in 15 min after physostigmine injection, whereas females performed 0.5 yawns in the same period. The difference is highly significant ($P < 0.002$) by the Mann-Whitney U test⁸. It may be recalled that Hall⁹, in his interesting description of the behaviour of monkeys towards mirror-images, in which 'yawning' or 'gaping' responses were very frequent, also observed that adult females 'rarely, if ever, yawned'.

Our results suggest that in the rat there is a central cholinergic mechanism, with 'muscarinic' receptors, underlying the act of yawning. The mechanism matures at a very early age, suggesting that it is localised at the lower levels of the brain stem. Later development of higher placed cholinergic mechanisms may determine that other effects evoked by cholinomimetic agents injected systemically might be hindering the expression of yawning in older rats. Intense and continuous scratching, or tremor and rigidity, as produced respectively by pilocarpine and physostigmine in rats aged over 10 d, or some other central or peripheral

Fig. 3 Blocking effect of scopolamine on physostigmine induced yawning. Arrows indicate the times of injections: at 0 time, physostigmine 0.10 mg per kg; at 15 min, scopolamine 5 mg per kg. The blocking effect of scopolamine is highly significant, $P < 0.001$ already 10 min after injection (Mann-Whitney U test⁶). Similar results were observed in another experimental series with scopolamine, 2.5 mg per kg.

actions affecting the level of vigilance, might be partially counteracting the yawn-inducing effect.

Myasthenia gravis serum reduces acetylcholine sensitivity in cultured rat myotubes

MYASTHENIA gravis is a neuromuscular disorder characterised by muscle weakness and fatigability. Muscle fibres from myasthenic patients have reduced amplitudes of endplate potentials and miniature endplate potentials^{1,2}. Early studies concluded that the disorder was presynaptic in origin because the postsynaptic chemosensitivity of the myasthenic muscle fibres was found to be normal³, but recent evidence indicates that myasthenia gravis is an autoimmune disease directed against the postsynaptic acetylcholine receptors⁴. Myasthenic serum globulin has been shown to bind to the acetylcholine receptors⁵, myasthenic muscle contains only 11–30% of α -bungarotoxin binding sites compared with normal muscle⁶, and iontophoretic studies showed that the acetylcholine sensitivity of the postsynaptic region of myasthenic muscle was markedly reduced⁷. But the failure of *in vitro* application of myasthenic serum to reduce the junctional or extrajunctional sensitivity of human, rat or frog muscle⁸ has raised doubt on the involvement of the

serum factor in the disease. In this report we show that the acetylcholine sensitivity of cultured rat myotubes is greatly reduced by *in vitro* application of myasthenic serum.

Skeletal muscle cells from newborn rats were explanted on collagen-coated 60 mm plastic Petri dishes according to the techniques of Yaffe⁹, at a plating density of 5×10^4 cells per dish. The cells were incubated in Dulbecco's modified Eagle's medium with 8 g l⁻¹ glucose, 9% foetal calf serum, 0.5% chick embryo extract and 50 μ g ml⁻¹ gentamycin. The cultures were maintained in a humidified atmosphere at 37 °C with 95% air and 5% CO₂. The myogenic cells began to fuse by day three and experiments were performed on 5 to 6 d old myotube cultures. Pooled sera from two patients with myasthenia gravis with a high titre of acetylcholine receptor antibody, and pooled sera from two normal individuals, were used. The normal or myasthenic serum was added to the 5–6 d old cultures containing the culture medium so as to give a sevenfold dilution of the serum.

Intracellular recordings were made using 3 M KCl-filled microelectrodes of 20–40 M Ω resistance, and the acetylcholine sensitivity measured iontophoretically using microelectrodes filled with 2 M acetylcholine and with a resistance of 50–200 M Ω . Recordings were made at 23 °C in the culture media except where otherwise stated. Acetylcholine receptors are located over the entire surface of cultured rat myotubes¹⁰, and the acetylcholine sensitivity was measured at several points on each myotube and the average sensitivity calculated. The sensitivity was expressed in mV nC⁻¹ and corrected for variation in membrane potential by multiplying the observed sensitivity by a factor $(E_s - E_R)/(E_M - E_R)$ where E_s is the standard membrane potential (–60 mV), E_R is the reversal potential for the acetylcholine response (0 mV) and E_M is the resting potential of the cell. The acetylcholine sensitivity was always measured for a depolarisation of 5 mV. It is particularly important to measure the acetylcholine sensitivity using a constant depolarisation when the sensitivity of different cells is being compared, since the sensitivity becomes higher with increasing depolarisation if the dose–response curve is nonlinear. We have found that the action of acetylcholine on rat myotubes does show such cooperativity, with a Hill coefficient of 1.5–2.0.

The acetylcholine sensitivity of the myotubes was initially measured in three separate sets of cultures with half of each set of cultures incubated for 22.5 h in normal serum, and the remainder incubated for the same period in myasthenic serum (Table 1). The myasthenic serum did not alter the resting potential of the myotubes, E_M of the normal and myasthenic cells averaging –47 mV and –45 mV respectively. The acetylcholine sensitivity of the cells treated with myasthenic serum was greatly reduced, however, in all of the three sets of cultures. The average acetylcholine sensitivity of the normal myotubes was 399 mV nC⁻¹, while that of the myasthenic myotubes was 27 mV nC⁻¹. Thus 22.5 h incubation in myasthenic serum caused a 93% reduction in the acetylcholine sensitivity.

Table 1 Reduction of acetylcholine (ACh) sensitivity of cultured rat myotubes by myasthenia gravis serum

Culture	No. of cells	Normal ACh		Myasthenia ACh		Inhibition of ACh sensitivity in myasthenic cells (%)
		E_M (mV)	sensitivity (mV nC ⁻¹)	E_M (mV)	sensitivity (mV nC ⁻¹)	
1	6	32	175	36	12	93*
2	5	50	825	46	52	94*
3	6	55	198	58	16	92*

The myotubes were incubated in normal serum or myasthenic serum for 22 h. Statistical significance was determined using a t test. E_M , membrane potential.

* $P < 0.001$.

Fig. 1 Acetylcholine sensitivity of cultured rat myotubes incubated for various times in myasthenic serum. Cultures were incubated for the times shown in normal or myasthenic serum, and the average value of the ACh sensitivity of six to eight myotubes cultured in normal or myasthenic serum was compared for each incubation time.

This reduction in sensitivity was irreversible, as perfusing for 3 h in normal saline caused no increase in the acetylcholine sensitivity. The acetylcholine potentials were also much slower in the myotubes treated with myasthenic serum. Normal myotubes gave 5 mV amplitude acetylcholine potentials with 10–20-ms rise times, whereas myotubes incubated with myasthenic serum gave 5 mV potentials with only 50–100-ms rise times. The acetylcholine sensitivity varied slightly at different points on both normal and myasthenic serum treated myotubes, but we found no evidence of acetylcholine receptors accumulating in patches or in caps at one area of the myotubes.

The rate of the decrease in acetylcholine sensitivity was very slow, and 2 h after incubation with the myasthenic serum, the sensitivity had decreased by only 25%. Figure 1 shows the time course of reduction of acetylcholine sensitivity, plotted on a semi-logarithmic scale. The reduction in sensitivity is approximately exponential, with a decay rate constant of 0.124 h^{-1} and a half-time of 5.6 h.

These results demonstrate that the serum of myasthenic gravis patients contains a factor which can reduce the acetylcholine sensitivity of cultured rat myotubes. Previous biochemical studies have shown that this factor is an IgG globulin which can bind to the acetylcholine receptor^{6,8}, although the IgG binding site is different from the acetylcholine binding site^{9,10}.

The slow rate and irreversible nature of the reduction in acetylcholine could be explained by the serum globulin being an irreversible antagonist and present in very low concentrations. The globulin has been shown, however, to produce an acceleration of the internalisation and/or degradation of the surface acetylcholine receptors of the cultured rat myotubes¹¹. It therefore seems likely that the binding of the globulin to the receptor does not prevent activation of the receptor by acetylcholine, but the reduction in acetylcholine sensitivity is caused by a decrease in the density of surface receptors on the myotubes.

Human myasthenic sera reduce acetylcholine sensitivity of human muscle cells in tissue culture

MYASTHENIA gravis is a muscle disease of man characterised by impaired neuromuscular transmission during repetitive motor nerve activity. Recent studies suggest that the defect in myasthenia gravis is post-synaptic and that myasthenic end-plates have a lower density of functional acetylcholine (ACh) receptors than normal end-plates. Thus end-plates from myasthenic patients show unusually small miniature end-plate potentials^{1,2}, are less sensitive than normal end-plates to iontophoretically applied ACh (refs 2, 3) and bind reduced amounts of α -bungarotoxin^{4,5}—a snake neurotoxin which is considered to bind specifically to nicotinic ACh receptors (see ref. 5). The presence of antibodies against ACh receptors in the sera of myasthenic but not of control patients^{6–10} suggests that anti-receptor antibodies might act in some way to decrease the number of functional receptors at the motor end-plate. Previous investigations, however, have failed to show conclusively that myasthenic sera contain a factor that reduces muscle ACh sensitivity^{3,11–13}. Here we show that myasthenic sera can reduce the ACh sensitivity of tissue cultured human muscle cells.

Explant cultures were made from muscle tissue of 12–16 week old foetuses. Cultures were grown at 37 °C on gelatin-coated tissue culture dishes in a modified Eagle's medium¹⁴ containing 10% foetal calf serum. Outgrowths of fibroblasts and myoblasts were seen after about 2 weeks and fused myotubes appeared after 3 weeks. The cultures selected for study were aged 4–7 weeks.

Iontophoretic application of ACh on to human myotubes evoked depolarising responses (Fig. 1). To compare ACh responses in cells of different resting potentials, ACh sensitivities were corrected to a resting potential of -50 mV by multiplying the recorded sensitivities by $-50/RP$, where RP is the resting potential (mV) of the cell under study. This correction factor assumes that the reversal potential for ACh responses is 0 mV (our unpublished observations). Cultures pre-incubated with 10% normal human serum at 37 °C for 1.5 h were used to provide a control value for ACh sensitivity. The mean sensitivity of myotubes exposed to three different normal sera was $1,080 \text{ mV nC}^{-1}$ (range of mean values, 800–1,200 mV nC^{-1}), which is similar to that of untreated cultures (about 950 mV nC^{-1}).

Six myasthenic sera were tested for their effect on myotube ACh sensitivity. Cultures were incubated with 10% serum at 37 °C for 1–1.5 h before electrophysiological examinations in serum free solution. As shown in Table 1, all the sera reduced myotube ACh sensitivity; in some cases the reduction was surprisingly large. This lowering of sensitivity is complement independent since a similar decrease was seen for one serum (no. 6 in Table 1) when complement was inactivated by heating the serum to 56 °C for 30 min. Myotube electrical properties which can influence the measured ACh sensitivity were similar in cultures exposed to either normal or myasthenic sera (Table 2). The lower sensitivity of myotubes treated with myasthenic sera must, therefore, result from an action of the serum on ACh receptors. Two sera from patients with

Fig. 1 Depolarising responses evoked by iontophoretic ACh pulses of 1 ms duration in myotubes treated with *a*, normal human serum and *b*, myasthenic human serum (serum 2 in Table 1). Recordings were made at 23 °C in a serum-free solution containing (mM) NaCl 150, KCl 5, CaCl₂ 10, HEPES-NaOH 5, pH 7.4. ACh was applied iontophoretically from pipettes filled with 3 M AChCl (resistances 180–400 MΩ using pulses of 5–20 nA amplitude and 0.5–10 ms duration). The position of the ACh pipette and the negative backing current required to prevent ACh diffusing out of the pipette were adjusted for each myotube to ensure a maximal ACh response. The resultant myotube depolarisations were recorded with an intracellular microelectrode filled with 4 M potassium acetate (resistances 20–40 MΩ). Recording pipettes were bevelled²⁷ to facilitate penetration of the small myotubes. ACh sensitivities were calculated as mV depolarisation per nanocoulomb (nC) of charge passed through the iontophoretic pipette.

Duchenne muscular dystrophy and amyotrophic lateral sclerosis were also tested; these had little or no effect on ACh sensitivity.

An immunoglobulin (IgG) fraction of myasthenic sera has been shown to block α -bungarotoxin binding to ACh receptors^{6,7}. To test if IgG is also involved in reducing ACh sensitivity, one serum was treated with goat anti-human IgG to precipitate IgG. The IgG-depleted serum showed a greatly reduced activity whereas serum treated with normal goat serum retained its full potency (see Table 1).

The effect of incubating cultures with myasthenic sera at a lower temperature was tested in four cases. Cultures were incubated with 10% serum for 1.5 h at 23 °C before estimating ACh sensitivities. All four sera reduced myotube sensitivity, though the decrease in each case was less than when cultures were exposed to myasthenic serum at 37 °C (Table 1). In two of these experiments, the cultures were subsequently incubated in serum-free medium at 37 °C for an additional 1 h. This resulted in a further decrease in sensitivity; the relative sensitivity of cells incubated with sera 3 and 6 fell from 0.41 and 0.47, respectively, to 0.18 in both cases. From this result we conclude that the temperature dependence of the serum effect is not due to different amounts of antibody binding at the two temperatures, but rather reflects a subsequent step in antibody action.

Experimentally raised anti-receptor antibodies increase the rate of receptor degradation in cultured rodent muscle cells¹⁵. This degradation, which resembles antigenic modulation^{16,17}, is temperature dependent and is blocked by metabolic inhibitors. The similar temperature dependence of human myasthenic serum action suggests that antibodies in the sera act to raise the receptor degradation rate in human myotubes. Indeed when five of the myasthenic sera were tested on cultured mouse muscle cells, all were found to increase the rate of ACh receptor degradation (Fig. 2). Receptor degradation follows first-order kinetics^{18–21},

Table 1 Effect of human sera on the ACh sensitivity of human myotubes

Serum	Anti-human ACh receptor titre ($\times 10^{-9}$ M)	Relative ACh sensitivity	
		23 °C	37 °C
Normal	<0.6	1.00	1.00
Myasthenic patient no.			
1	30	0.46	0.02
2	8	—	0.39
3	446	0.69, 0.41	0.20
4	332	0.71	0.40
5	143	—	0.53
6	83	0.47	0.03
6, complement inactivated	—	—	0.06
6, IgG precipitated with goat anti-human IgG	—	—	0.65
6, plus normal goat serum	—	—	0.08
Duchenne muscular dystrophy	<0.6	—	0.95
Amyotrophic lateral sclerosis	<0.6	—	1.19

Relative ACh sensitivities of myotubes after exposure to 10% human sera at either 23 or 37 °C for 1–1.5 h. Sensitivities are expressed as the ratio (test serum ACh sensitivity–normal serum ACh sensitivity). For each serum sensitivities were estimated in 6–20 cells. The unity value for normal serum represents the mean sensitivity of six experiments testing three sera. Anti-human ACh receptor titres were estimated using an immunoprecipitation technique described elsewhere²⁸. Titres are expressed as moles of ¹²⁵I- α -bungarotoxin bound to human ACh receptors precipitated per litre of serum. In one experiment, serum 6 was depleted of IgG by precipitation with goat anti-human IgG serum; complement was inactivated in both sera. The resultant supernatant was dialysed against culture medium for 24 h before adjusting the volume to give the equivalent of 10% human serum in medium. Some reduction in sensitivity was seen when this IgG-depleted serum was tested. It seems likely that this is due, at least in part, to the lower input impedances of the myotubes in this experiment (about 40% of other values). To test for any general effects of goat serum on myasthenic serum action, the immunoprecipitation protocol was repeated using normal goat serum in place of immune goat serum. In this case no precipitate was formed and the full reduction in ACh sensitivity was seen.

whereas the appearance of new receptors is a linear process^{19,21,22}. An antibody-induced acceleration of receptor degradation without a compensatory increase in the rate of synthesis would therefore result in a lowered receptor density; this could explain the reduced ACh sensitivity of cells exposed to myasthenic sera. A possible objection to this idea is the observation that while the ACh sensitivity of myasthenic serum-treated cells declines within 60–90 min, the accelerated secretion of degraded ¹²⁵I- α -bungarotoxin, which is used to assay receptor degradation, occurs after a lag of several hours (Fig. 2 and ref. 15). This lag, however, includes the time not only for induced receptor internalisation but also for receptor catabolism and secretion of the degraded toxin. The internalisation of antibody-complexed cell surface components can occur within 1 h (ref. 23) and the secretion of degraded ¹²⁵I- α -bungarotoxin occurs in

Table 2 Myotube electrical properties after exposure to human serum at 37 °C

	Resting potential (mV)	Input impedance (MΩ)	Membrane time constant (ms)
Normal sera	-47.9 $\pm$ 4.4	244 $\pm$ 76	71 $\pm$ 17
Myasthenic sera	-47.7 $\pm$ 3.7	225 $\pm$ 28	77 $\pm$ 8

Values are expressed as mean $\pm$ s.e. of between experiment results. The measured resting potentials represent the potentials at which ACh sensitivities were measured and probably underestimate the true value. Cell input impedances and membrane time constants were measured by passing hyperpolarising pulses of 0.2 nA amplitude and up to 1 s duration through the recording electrode using a bridge circuit built into the electrometer (M-4A, W.P. Instruments). As the time constant of the myotube membrane was much greater than that of the recording system, the bridge circuit was easily balanced with the electrode inside the cell. The large input impedances reflect the small size of the cells (5–20 μ m diameter) rather than any unique membrane properties.

normal conditions with a lag of about 1 h (ref. 19). An antibody-induced modulation of ACh receptors may, therefore, lower the surface receptor density within the 1–1.5 h incubation periods used in the electrophysiological experiments.

Bound antibodies could also reduce ACh sensitivity by modifying the properties of activated ACh receptors. Preliminary 'ACh noise' experiments indicate that in human myotubes exposed to myasthenic serum the charge passed during a single channel opening is reduced by about 30% (S.B., R.W.K. & J. Rice, unpublished). A similar reduction in the charge transferred per open channel is seen in cultured rat myotubes treated with experimentally raised antibodies¹⁵. In addition, antibodies might act by completely inactivating some ACh receptors. Such direct actions of antibodies on receptor function may explain the lowered ACh sensitivity of cells exposed to myasthenic serum at 23 °C and also contribute to the larger reduction seen with incubations at 37 °C.

Our demonstration that myasthenic sera can reduce muscle ACh sensitivity contrasts with the results of earlier studies. As anti-receptor antibodies show a higher affinity for homologous than for heterologous receptors^{24,25} the lack of any serum effect in some previous studies may be due to the use of non-human muscle cells. In addition, more labile receptors such as those in tissue cultured cells^{19,21} may be necessary to show a rapid reduction in sensitivity arising

from receptor modulation. The loss of the more stable end-plate receptors^{18,20,26} through modulation may occur too slowly to cause any decrease in ACh sensitivity during short term experiments. This would explain the apparent absence of any blocking action of myasthenic sera at human end-plates *in vitro*³.

Our results suggest that the low ACh sensitivity of human myasthenic end-plates results primarily from the action of antibodies. Further experiments will be necessary to determine if myasthenic sera do decrease human end-plate sensitivity in appropriate conditions and to elucidate further the importance of receptor modulation in depressing ACh sensitivity.

We thank Dr E. Lambert for providing the foetal muscle tissue and Dr J. Lindstrom for human sera. This study was supported by the Muscular Dystrophy Associations of America, the NIH and the Canadian MRC.

Fig. 2 Loss of ¹²⁵I-α-bungarotoxin from mouse muscle cells. Cells of the clonal cell line BC₃H-1 (refs 15, 21) were incubated in 10⁻⁸ M ¹²⁵I-α-bungarotoxin for 2 h at 21–23 °C in medium containing 0.2% foetal calf serum. Unbound toxin was then removed by washing the cells four times in medium with 0.2% foetal calf serum. The cultures were then incubated at 37 °C in medium containing various sera and the amount of ¹²⁵I released into the medium measured at various times. ¹²⁵I release is expressed as the ratio ¹²⁵I released/amount of ¹²⁵I initially bound to cells. Each point is the mean of duplicate samples. Fractionation of the medium on a Biogel P2 column showed that the extra ¹²⁵I released in the presence of myasthenic serum is due to an increase in the release of low molecular weight ¹²⁵I-labelled material and not to an induced dissociation of intact bungarotoxin. ◇, Foetal calf serum (FCS, 12%); ●, 10% normal human serum + 2% FCS; ○, 10% myasthenic human serum + 2% FCS. For comparison the effect on these cells of serum from rats immunised with electric eel ACh receptor is also shown (▲, 10% rat serum + 2% FCS, final titre 1.1 × 10⁻⁸ M anti-rat receptor). In a further experiment 10% human serum was added to cultures in the presence of 10⁻⁸ M ¹²⁵I-α-bungarotoxin and 10⁻³ M curare. In these conditions toxin binding to the muscle cells is inhibited by more than 90%. After 600 min the medium was removed and fractionated. No degradation of the ¹²⁵I-α-bungarotoxin was noted, indicating that the myasthenic serum, by itself, does not degrade toxin and that toxin degradation only occurs after binding to ACh receptors.

Long term β-adrenergic blockade reduces tyrosine hydroxylase and dopamine β-hydroxylase activities in sympathetic ganglia

β-ADRENOCEPTOR antagonists are now well established in the treatment of hypertension but the mechanism by which they reduce blood pressure is not understood¹. There is clearly more involved than an immediate blockade of the cardiovascular β-adrenergic receptors, since intravenous (i.v.) infusion of propranolol in man reduces cardiac output but has no effect on arterial blood pressure^{2,3}. The full hypotensive effect of β-adrenergic blockers is delayed⁴, and is associated with a reduction in peripheral resistance^{2,3}. The hypotensive action of these drugs is nevertheless predominantly related to their common property of β-adrenergic receptor blockade, as they all produce similar

falls in blood pressure⁵ despite their differing ancillary properties⁶ and effects on plasma renin activity⁷. It has been suggested that the hypotensive effect of propranolol is due to a central inhibition of sympathetic activity, since i.v. propranolol reduces preganglionic sympathetic nerve activity in rabbits⁸. But practolol, an effective antihypertensive which penetrates the central nervous system poorly⁹, has no such acute effect¹⁰. The possibility has yet to be considered that the hypotensive action common to all β -adrenoceptor antagonists is directly related to a slowly developing reduction in sympathetic activity and hence in peripheral resistance. Long term increases or decreases in the activity of sympathetic neurons are specifically reflected by changes in the concentration of the nor-adrenaline-synthesising enzymes tyrosine hydroxylase and dopamine β -hydroxylase contained in the cells¹¹. We report here that prolonged treatment with β -adrenoceptor antagonists causes a slow-onset reduction in the concentration of these enzymes in the superior cervical ganglia of rabbits. This decrease in sympathetic activity may in part explain the hypotensive effect of long-term β -blockade.

Rabbits (2–3 kg) were injected twice daily subcutaneously (s.c.) with ($\pm$)-propranolol for 3, 6 or 12 d, or with saline. The degree and duration of β -blockade achieved with this dosage regime have been previously reported¹². In further experiments animals were dosed for 24 d with either ($\pm$)-propranolol, (+)-propranolol (ICI), ($\pm$)-metoprolol, ($\pm$)-acebutolol, ($\pm$)-practolol in equipotent dosage or with saline. Animals were stunned 18–24 h after the final injection and the left and right superior cervical ganglia were rapidly removed and homogenised separately in 1 ml of 0.3 M sucrose. Tyrosine hydroxylase activity of homogenates was measured by the method of Levitt *et al.*¹³ and dopamine β -hydroxylase activity by that of Molinoff *et al.*¹⁴. Protein was determined by the method of Lowry *et al.*¹⁵. To compare the effect of decentralisation on ganglionic enzyme activity with that of prolonged β -adrenoceptor blockade, the left superior cervical preganglionic trunk was cut and ligated under nembutal anaesthesia in four rabbits. After a recovery period of 12 d both superior cervical ganglia were removed and the activities of their enzymes were measured.

Propranolol has no acute effect on tyrosine hydroxylase activity in sympathetic ganglia¹⁶ and similarly we found no significant change in ganglionic tyrosine hydroxylase or dopamine β -hydroxylase activities after 3 d of propranolol treatment. In contrast, activities of both enzymes were reduced by pretreatment with propranolol for 6 d (Fig. 1),

Fig. 1 Effect of chronic treatment with ($\pm$)-propranolol on activities of tyrosine hydroxylase (●) and dopamine β -hydroxylase (▲) in rabbit superior cervical ganglia. Rabbits were injected s.c. twice daily with ($\pm$)-propranolol 4 mg per kg body weight for 3 d ($n = 4$), 6 d ($n = 4$) or 12 d ($n = 4$) or with saline 1 ml per kg ($n = 6$). Points are mean $\pm$ s.e.m. of 8–12 determinations. Enzyme activities for controls are shown at day 0.

and after 12 d tyrosine hydroxylase and dopamine β -hydroxylase activities were 25% lower than in controls. To determine whether this action was due to β -receptor blockade and not to any subsidiary properties of the drugs, rabbits were treated for 24 d with four β -adrenoceptor antagonists chosen for their differing properties of cardio-selectivity, intrinsic sympathomimetic activity and membrane-stabilising action⁶. Despite these differences all four drugs produced comparable reductions in enzyme activities (Table 1). The fall in dopamine β -hydroxylase activity was similar for all drugs, but the reduction in tyrosine hydroxylase activity was greatest with propranolol, and least with practolol. This cannot be due to the relatively powerful membrane-stabilising activity of propranolol since (+)-propranolol, which has negligible β -blocking activity but the same local anaesthetic potency as ($\pm$)-propranolol, did not alter enzyme activities (Table 1). The difference between propranolol and practolol may be related to the high lipid solubility and central nervous system (CNS) penetration of propranolol¹⁷ compared with that of practolol⁸.

Table 1 Effect of chronic treatment with β -adrenoceptor antagonists on tyrosine hydroxylase and dopamine β -hydroxylase activities in rabbit superior cervical ganglia

	Tyrosine hydroxylase (% of control)	Dopamine β -hydroxylase (% of control)
($\pm$)-Propranolol	64 $\pm$ 8*	70 $\pm$ 6*
(+)-Propranolol	91 $\pm$ 10	103 $\pm$ 8
($\pm$)-Metoprolol	70 $\pm$ 7*	73 $\pm$ 6*
($\pm$)-Acebutolol	79 $\pm$ 7†	64 $\pm$ 13†
($\pm$)-Practolol	85 $\pm$ 5‡	73 $\pm$ 5*

Rabbits were injected s.c. twice daily for 24 d with either saline 1 ml per kg ($\pm$)-propranolol 4 mg per kg, (+)-propranolol 4 mg per kg, ($\pm$)-metoprolol 6 mg per kg, ($\pm$)-acebutolol 10 mg per kg or ($\pm$)-practolol 10 mg per kg body weight. Enzyme activity is expressed in terms of nmol dopa per 15 min per mg protein (tyrosine hydroxylase) or nmol phenylethanolamine per h per mg protein (dopamine β -hydroxylase) given as percentage of control activity. Values are mean $\pm$ s.e.m. of 10–12 determinations.

* $P < 0.001$.

† $P < 0.02$.

‡ $P < 0.05$.

The effect of decentralisation of superior cervical ganglia is shown in Table 2. Twelve days after decentralisation, activities of tyrosine hydroxylase and dopamine β -hydroxylase were 26% and 29% less than in contralateral control ganglia, a reduction comparable with that caused by prolonged β -adrenergic blockade.

Adaptation to increases in sympathetic activity by trans-synaptic induction of tyrosine hydroxylase and dopamine β -hydroxylase is due to increased synthesis of enzyme protein¹¹. This process is slow, and first detectable 18 h after increased preganglionic activity¹⁸. Conversely it is thus possible that β -adrenoceptor antagonists cause a sudden reduction in preganglionic nerve activity, which is detected in these experiments as a reduced enzyme activity in the sympathetic neurons. As we observed no significant change in enzyme activities after 3 d of propranolol treatment, however, it is more probable that continuing β -adrenergic blockade causes a gradual reduction in preganglionic sympathetic activity mirrored by the reduction in the activities of the specific neuronal enzymes. Strikingly, we found that interruption of preganglionic impulse flow by decentralisation resulted in a very similar fall in the enzyme activities in the superior cervical ganglia. A possible interpretation of this is that chronic β -adrenergic blockade is virtually abolishing all preganglionic nervous activity. Of course, we cannot know if this is so because it is not known by how much the nervous activity must be reduced to detect the consequent decrease in enzymic activity. If preganglionic

Table 2 Effect of decentralisation on the tyrosine hydroxylase and dopamine β -hydroxylase activities in rabbit superior cervical ganglia

	Tyrosine hydroxylase (nmol dopa per 15 min per mg protein)	Dopamine β -hydroxylase (nmol phenylethanol- amine per h per mg protein)
Control (R)	2.02 $\pm$ 0.25	209 $\pm$ 9
Decentralised (L)	1.47 $\pm$ 0.18*	149 $\pm$ 16*

Left superior cervical ganglia were decentralised in four rabbits, and 12 d later the activities of the enzymes were determined. Values given are the mean $\pm$ s.e.m. of four ganglia. To ensure that the ganglia were decentralised choline acetyltransferase activity was determined in the homogenates according to the method of Fonnum²⁰. The activity of this enzyme in the decentralised ganglia was less than 10% of the contralateral controls.

* $P < 0.01$ (paired t test).

activity is reduced by blockade of central β -adrenoceptors* our results would suggest that polar 'cardioselective' drugs may reach significant concentrations in the CNS during steady-state dosing. Alternatively, the reduction in sympathetic activity by chronic β -adrenergic blockade may be peripherally mediated either through a long term alteration of afferent autonomic input, resulting in an adaptive reduction in sympathetic outflow^{4,10}, or through continued blockade of a prejunctional β_1 -adrenoceptor, activation of which increases noradrenaline release¹⁹.

It seems reasonable, though, to conclude that prolonged β -adrenergic blockade produces a slow-onset reduction in the activity of the sympathetic nervous system. Since tyrosine hydroxylase is the rate-limiting enzyme in the biosynthesis of noradrenaline²¹, the amount of neurotransmitter available for release is most probably also reduced. Significant reductions in the ganglionic activities of tyrosine hydroxylase and dopamine β -hydroxylase were seen with several different β -adrenoceptor antagonists, all of which are clinically effective antihypertensives despite their differing subsidiary properties. We therefore suggest that this delayed reduction in sympathetic activity contributes to the hypotensive action of β -adrenoceptor antagonists.

β Endorphin inhibits ACh turnover in nuclei of rat brain

NARCOTIC drugs modify cholinergic mechanisms in central and peripheral nervous systems¹, and analgesic doses of morphine, meperidine, viminal R₂ and azidomorphine decrease acetylcholine (ACh) turnover rate (TR_{ACh}) in selected brain nuclei^{2,3}. This suggests that endogenous opiate receptor agonists regulate cholinergic mechanisms in some brain nuclei². Among the endogenous opiate receptor agonists, β endorphin is particularly interesting because it is more active than morphine in causing analgesia and catalepsy⁴. This polypeptide and α endorphin share some structural similarities which correspond to fragments 61-76 and 61-91 of β lipotropin, respectively⁵. We have investigated whether α and β endorphin also mimic the action of morphine on TR_{ACh} of selected brain nuclei. We have found that analgesic doses of β endorphin injected intraventricularly decrease TR_{ACh} in cortex, hippocampus, nucleus accumbens and globus pallidus but not in nucleus caudatus. This decrease of TR_{ACh} was antagonised by naltrexone. In contrast, α endorphin failed to cause analgesia or to decrease TR_{ACh} in all brain nuclei studied.

Endorphins were injected into unanaesthetised rats (150 g male Sprague-Dawley, Zivic Miller, Allison Park, Pennsylvania) through polyethylene cannulae permanently implanted in the lateral ventricles, 2 d before the experiments. Each polypeptide was dissolved immediately before use in 10 μ l of saline. The analgesic activity of α and β endorphins was measured by the tail flick method⁷ 30 min after intraventricular injection.

TR_{ACh} was measured by intravenous infusion of phosphorylcholine (ammonium salt) (15 μ mol min⁻¹) for 9 min beginning 21 min after injection of endorphins. During the administration of phosphorylcholine rats were restrained in plastic cages. TR_{ACh} was calculated from the deuterium enrichment of choline (Ch) and ACh as before⁸. Rats were killed with a high-intensity microwave beam focused on the head⁹. Brains were removed and sliced into 400- μ m thick coronal sections and punches were made in the head of the nucleus caudatus, in the pars dorsalis of the hippocampus, in the globus pallidus, nucleus accumbens and parieto-occipital cortex. The position of the polyethylene cannulae was controlled during slicing.

The enrichment in deuterium of ACh and Ch extracted from various nuclei was measured mass fragmentographically⁸. From these values we calculated the fractional rate constant for the efflux of deuterated Ch and ACh. This value multiplied by the ACh content of each brain region gave TR_{ACh} (ref. 10). Table 1 shows that β endorphin inhibited TR_{ACh} in the hippocampus, nucleus accumbens, globus pallidus and cortex. But, like morphine, this polypeptide failed to change TR_{ACh} in the nucleus caudatus. From the data of Table 2, the dose of β endorphin that, given intraventricularly, reduced TR_{ACh} in hippocampus by 50%, was calculated to be approximately 0.2 nmol. From previous reports^{2,3}, the dose of morphine that caused similar changes in TR_{ACh} in the hippocampus was about 33 nmol g⁻¹, given intraperitoneally. Even allowing for differences due to the different route of drug administration, there is no doubt that β endorphin is several times more active than morphine in decreasing the TR_{ACh} of the hippocampus. Using the tail flick test, we have confirmed⁴ that β endorphin has analgesic activity (Table 2): 1.8 nmol per brain caused 50% of maximal analgesia⁷. Similar analgesic activity was obtained with morphine (35 nmol g⁻¹)². Thus, as shown for morphine, doses of β endorphin which elicited analgesia also reduced hippocampal TR_{ACh}. Naltrexone (14 μ mol kg⁻¹, given intraperitoneally) completely prevented the analgesic action and

Table 1 Effects of α and β endorphins on TR_{ACD} in nuclei of rat brain

Brain nuclei	Saline	β Endorphin (2.9 nmol per brain)	β Endorphin + naltrexone	α Endorphin (11.5 nmol per brain)
Cortex	1.0 $\pm$ 0.10	0.35 $\pm$ 0.059*	1.1 $\pm$ 0.14	0.97 $\pm$ 0.14
Hippocampus	3.9 $\pm$ 0.70	0.65 $\pm$ 0.099*	4.9 $\pm$ 2.0	3.7 $\pm$ 0.64
Globus pallidus	2.6 $\pm$ 0.40	1.0 $\pm$ 0.18*	2.9 $\pm$ 0.65	2.13 $\pm$ 0.19
Nucleus accumbens	4.9 $\pm$ 1.0	2.02 $\pm$ 0.35*	4.7 $\pm$ 1.0	4.1 $\pm$ 0.47
Nucleus caudatus	8.6 $\pm$ 0.80	8.4 $\pm$ 1.6	9.9 $\pm$ 1.6	6.7 $\pm$ 2.0

Data expressed in nmol per mg protein per h.

Endorphins were injected intraventricularly 21 min before intravenous infusion of phosphoryl (d_6) choline; naltrexone (14 μ mol per kg) was injected intraperitoneally 15 min before the endorphins. The ACh content in nmol per mg protein was 0.16 $\pm$ 0.03 in cortex, 0.30 $\pm$ 0.020 in hippocampus, 0.73 $\pm$ 0.060 in nucleus caudatus, 0.45 $\pm$ 0.034 in globus pallidus and 0.79 $\pm$ 0.045 in nucleus accumbens; the Ch content was 0.35 $\pm$ 0.030 in cortex, 0.33 $\pm$ 0.032 in hippocampus, 0.28 $\pm$ 0.020 in nucleus caudatus, 0.30 $\pm$ 0.020 in globus pallidus and 0.50 $\pm$ 0.035 in nucleus accumbens. The endorphins and naltrexone failed to change ACh and Ch content. Each value is the mean $\pm$ s.e.m. of 10 assays in the saline-treated group, and of five assays in the other groups.

* $P < 0.01$ compared with the saline-treated group.

the decrease of TR_{ACh} elicited by β endorphin. α Endorphin, in a dose of 11.5 nmol per brain, had no analgesic activity and failed to change TR_{ACh} in any of the five brain areas studied (Table 1). Thus β endorphin was biochemically and behaviourally more potent than α endorphin. This finding is in line with other reports showing the same order of potency in the displacement of ^3H -etorphine from synaptosomal preparations of rat brain¹¹ or in behavioural effects⁴.

Table 2 Analgesia and TR_{ACh} in rat hippocampus after various doses of β endorphin

Dose of β endorphin (nmol per brain)	TR_{ACh} (nmol per mg protein per h)	Analgesia (% of maximum)
0 (saline)	4.1 $\pm$ 0.90	0
0.029	3.8 $\pm$ 0.70	7 $\pm$ 1
0.29	1.0 $\pm$ 0.15*	23 $\pm$ 5
1.45	—	36 $\pm$ 5
2.9	0.65 $\pm$ 0.099*	75 $\pm$ 15

Each value represents mean $\pm$ s.e.m. of 10 assays in saline-treated rats and five assays in endorphin-treated rats. Analgesia was evaluated by the tail flick test⁷.

* $P < 0.01$.

β Endorphin is an active, naturally occurring opiate receptor agonist, which, like morphine, decreases TR_{ACh} in doses which increase the threshold for pain sensation. The data reported here imply that if endogenous β endorphin were to be released from presynaptic terminals in the vicinity of opiate receptors located in the membrane of cholinergic neurones, it would decrease the metabolic rate of ACh and presumably decrease the rate of firing of these neurones.

Calcium-dependent presynaptic action of substance P at the frog neuromuscular junction

SUBSTANCE P, an 11 amino acid peptide found in many areas of the nervous system¹, has been proposed to be the excitatory transmitter between primary afferents and motoneurons². A depolarising action of substance P on spinal motoneurons and primary afferents has been demonstrated^{3–6}. But, an initial reduction of response preceding an increased spinal reflex discharge and a reduction of the motoneurone excitatory postsynaptic potential has also been seen in response to substance P (refs 4, 5). In addition, both excitatory and inhibitory effects of substance P on firing of cuneate and cortical Betz cells have been reported^{7,8}. In the hatchetfish Mauthner fibre–giant fibre synapse, substance P has a pronounced presynaptic effect⁹. We have further investigated the effects of substance P at a synapse in which the electrophysiological characteristics and transmitter are known, the ionic constituents of the Ringer can be manipulated and quantal analysis is possible—the neuromuscular junction of the frog. We report here that substance P has a potent presynaptic effect on transmission at this synapse which is composed of an initial phase in which transmission is depressed, followed by a prolonged period in which excitability and quantal release are increased.

The cutaneous pectoris muscle and nerve of the frog, *Rana pipiens*, was used. With the exception of experiments (noted below) in which the Ca^{2+} concentration was varied, the Ringer contained 115 mM NaCl, 2 mM KCl, 0.6 mM CaCl and 5 mM MgCl buffered to pH 7.3 with Tes (Sigma). Substance P (Bachem) or eleodisin (eleodisin related peptide, Sigma) was added to the control Ringer, bath applied, and removed with repeated washing after 2–5 min exposure to the preparation. Substance P was used in the majority of the experiments; however, no difference in experimental results was seen when equivalent concentrations of eleodisin were used. Spontaneous miniature endplate potentials (m.e.p.p.) used for frequency and amplitude analysis were recorded from different experiments than those using evoked endplate potentials (e.p.ps). The e.p.ps were evoked by nerve stimulation at 1 per s for 1 min and stimulation discontinued between sampling periods. The m.e.p.ps used for quantal analysis were recorded before the evoked re-

sponse. Quantal content was calculated as e.p.p./m.e.p.p. amplitude. Control experiments of equal duration and stimulation pattern were run. Data analysis was as detailed previously⁹.

The effects of substance P on synaptic transmission were dose dependent and at high doses only depressant effects were seen. At 10^{-4} M concentration, m.e.p.p. amplitude and frequency, e.p.p. amplitude and quantal content were all reduced with the maximum depression being reached at 5–10 min after application. The m.e.p.p. amplitude usually showed a complete recovery but m.e.p.p. frequency, e.p.p. amplitude and quantal content seldom recovered to control values even 1–2 h after application. At lower peptide concentrations (10^{-5} M, 10^{-6} M), recovery of synaptic depression and a second phase of increased synaptic efficacy was seen. An initial depression of synaptic transmission was seen with a maximum depression at 5–10 min and a return to control values after 30–40 min followed by a prolonged second phase of increased synaptic efficacy in which the e.p.p. amplitude and quantal content showed increases of up to five times control values. This phase did not decline to control values until 2–3 h or more after peptide application. The m.e.p.p. amplitude showed little or no change at the lower peptide concentrations. The m.e.p.p. frequency changes usually showed a small frequency reduction in the initial phase and either no change or a small frequency reduction in the second phase. The latency of onset of the peptide effect was approximately 30 s at all peptide concentrations. No change in the resting potential of the muscle fibre was seen at any peptide concentration.

Figure 1 illustrates a typical response to application of 10^{-5} M substance P bath applied at the first arrow and removed at the second arrow. Both e.p.p. amplitude and quantal content reach a maximum reduction by 10 min,

Fig. 1 Representative example of the effect of substance P (10^{-5} M) on *a*, e.p.p. amplitude and *b*, quantal content. Substance P Ringer is applied to the bath at the first arrow and removed at the second. Data plotted as means and standard deviations at each indicated time period.

Fig. 2 Multiple e.p.ps recorded from a muscle fibre following substance P application. Substance P (10^{-5} M) is applied after control record and removed by washing 5 min later. The time course of ensuing synaptic depression and recovery is the same as in Fig. 1 but on recovery, multiple e.p.ps are produced in response to a single stimulus to the motor nerve. Figures in first column are composed of five consecutive sweeps; those in the last column are single sweeps. Note difference in time scale for first and last columns. Middle column contains samples from the same fibre of m.e.p.ps at different time periods to illustrate lack of peptide effect on e.p.p. amplitude.

recover to control values at 40 min and then show a prolonged period of increase which, at 3 h post application when the cell was lost, was declining but had not yet returned to control values. In some experiments, during the phase of increased synaptic efficacy, multiple e.p.ps were produced in response to a single stimulus to the presynaptic axon. This is presumed to be due to multiple firing of the motor axon. In Fig. 2, a maximum of 11 e.p.ps are seen in response to a single stimulus to the motor axon. The multiple firing begins as the e.p.p. amplitude returns to control values and lasted, in this case, until the cell was lost 3 h after peptide application. The m.e.p.p. amplitude (middle column) shows no change during the entire experimental period. Although not apparent from the small m.e.p.p. samples in these records, m.e.p.p. frequency showed only a small reduction in frequency after peptide application, lasting for the duration of the experiment.

The initial phase of peptide-induced synaptic depression seems to be calcium dependent (Fig. 3). The reduction in e.p.p. amplitude produced by 10^{-4} M substance P can be blocked by increasing the Ca^{2+} in the Ringer. When the Ca^{2+} is increased in steps from 0.6 to 3.6 mM, an increase in e.p.p. amplitude with increase in Ca^{2+} is seen until at 3.6 mM Ca^{2+} no effect of the peptide on e.p.p. amplitude is seen: curare (1.5 mg l^{-1}) was added to the Ringer to prevent muscle twitching in response to nerve stimulation at high Ca^{2+} levels. In other experiments, in curare-free Ringer, no changes in m.e.p.p. frequency were seen when the peptide at 10^{-4} M was applied to the bath in Ringer containing 3.6 mM Ca^{2+} . The effect of increased calcium concentrations on the second phase of the response was not tested in these experiments. In addition to the above neurophysiological findings of a calcium dependency, a substance P-mediated reduction in ^{45}Ca uptake by isolated synaptosomes and an increase in ^{45}Ca sequestration by

Fig. 3 Calcium dependence of the initial phase of synaptic depression produced by substance P. As calcium is increased, the reduction in e.p.p. amplitude produced by the peptide is decreased until, at twice normal Ringer calcium concentration (3.6 mM), the peptide has no effect on e.p.p. amplitude. Substance P concentration is 10^{-4} M. Each point is the average of five trials.

mitochondria isolated from rat brain has been found (unpublished data, A. Blitz, K. Dasse, and D. Sack). Effects on calcium uptake at these two sites both act to reduce free calcium in the presynaptic terminal. This, together with the above demonstrated blocking of the initial phase peptide effects by increased calcium in the Ringer, suggests that the synaptic depression seen in response to substance P is calcium dependent.

A possible mechanism of action for the substance P action reported here is a modulation of calcium-dependent potassium conductance which has been shown to regulate firing rates in several systems¹⁰⁻¹³. When delayed rectification is blocked in the frog neuromuscular junction, regenerative calcium dependent responses are seen in the presynaptic region¹⁴. A calcium-mediated potassium conductance has been suggested as a regulator of rhythmic and long term neural processes¹⁵. That substance P may be a physiological means of regulating this process is consistent with the above data. One could then postulate that the peptide functions to bias the output produced by the more static short term information transfer of the conventional transmitters.

Postsynaptic receptors are not essential for dopaminergic feedback regulation

ANTIPSYCHOTIC drugs (neuroleptics) which block central dopamine (DA) receptors increase the synthesis and metabolism of striatal DA and the firing of dopaminergic neurones in the substantia nigra. These effects have been postulated to be secondary to the drug-induced blockade of striatal postsynaptic DA-receptors and mediated by a negative feedback loop impinging on nigral DA-neurones^{1,2}. However, the existence of alternative mechanisms has been recently postulated³⁻⁵. In particular, it has been suggested that neuroleptics stimulate dopaminergic firing by blocking nigral DA-receptors, thus relieving DA-neurones from the inhibitory action of DA released from dopaminergic dendrites (self-inhibition)⁶. Indirect support for this possibility derives from the recent discovery of a DA-sensitive adenylate cyclase within the substantia nigra⁷⁻⁹. We report here that destruction of striatal DA-sensitive adenylate cyclase by kainic acid¹⁰ fails to reduce the effect of neuroleptics and of apomorphine, a DA-receptor agonist¹¹, on striatal DA-metabolism. These data indicate that an interaction with postsynaptic DA receptors is not essential for the changes in DA-metabolism produced by neuroleptics and apomorphine and provide *in vivo* evidence for the existence of a dopaminergic negative feedback independent from postsynaptic DA-receptors.

Male Sprague-Dawley rats (290-310 g) were anaesthetised with Equithesin and placed on a stereotaxic frame (Kopf); kainic acid (Sigma) dissolved in 1 μ l of saline was injected in 2 min in the caudate of one side while that of the other side received the same volume of saline. Coordinates were A 2.2, V 2.8, L 5.0 of Pellegrino and Cushman¹².

Ten days post-surgery, rats were killed and the striata of each side dissected out and homogenised in Tris-maleate buffer for adenylate cyclase assay¹³ or frozen at -20°C until analysed for DA and 3,4-dihydroxyphenyl acetic acid (DOPAC)¹⁴ in order to estimate DA-metabolism¹⁵. The brains of three rats were perfused with formaldehyde, cut by cryostat into 40- μ m slices and stained by cresylviolet in order to ascertain the extent and topography of the lesion.

Haloperidol (Janssen) and fluphenazine (hydrochloride salt, Squibb), were injected intraperitoneally (i.p.) while apomorphine, hydrochloride, Sandoz) was administered subcutaneously (s.c). Protein was measured by the method of Lowry *et al.*¹⁶ using bovine serum albumin as a standard.

Figure 1 is a micrograph of rat striatum from the side injected with kainic acid (3 μ g 10 d previously), as compared with the contralateral side injected with saline. It seems that in the side injected with kainic acid neuronal perikarya are markedly reduced in number while only a slight gliosis is present. The loss of neuronal perikarya affected more than 80% of the caudate-putamen, the nucleus interstitialis striae terminalis and about 60% of the nucleus accumbens, but did not involve the adjacent cerebral cortex and thalamus.

As soon as the rats awakened from anaesthesia they showed continuous turning contralateral to the kainic-injected side and intermittent whole body-rocking. This symptomatology lasted for at least 3-4 h. By 24 h post-surgery, rats displayed homolateral torsion of the body and turning which, although diminished, was still present 10 d post-surgery. At this time, administration of apomorphine (0.1 or 0.5 mg per kg body weight s.c.) stimulated the homolateral turning while haloperidol (0.3 mg per kg i.p.) reversed the turning into a contralateral one.

In agreement with the results of McGeer *et al.*¹⁰ we found that the unilateral intrastratial injection of 3 μ g of kainic acid resulted in a 40% decrease of basal adenylate cyclase activity in homogenates of kainic-injected striatum. Moreover, in these homogenates DA completely failed to stimulate the adenylate cyclase activity even when added at a concentration of 100 μ M, which maximally stimulated adenylate cyclase of striatal homogenates from the control side.

Unilateral administration of kainic acid did not modify DA-concentrations but resulted in a 100% increase of DOPAC levels in the lesioned striatum (see Fig. 2).

Parenteral administration of haloperidol increased, and of apomorphine decreased DOPAC levels both in the kainic-injected and in the control striatum. As Fig. 2 shows, 90 min after a maximally effective dose of haloperidol (0.3 mg per kg), DOPAC concentrations increased by the same amount in the kainic-injected and in the control striatum, thus reaching significantly higher levels in the lesioned striatum. A lower dose of haloperidol (0.100 mg per kg) caused a much greater accumulation of DOPAC in the kainic injected striatum than in the control side and the absolute increase of DOPAC in the kainic-injected side was more than twice that in the control one. Finally, a dose of haloperidol of 0.030 mg per kg failed to produce a significant increase of DOPAC in the control

Fig. 2 Effect of haloperidol (H) and apomorphine (A) on DOPAC concentrations in control and kainic-lesioned striatum. Rats were injected with 3 μ g of kainic acid in the right striatum and with saline in the left one. After 10 d, rats were given haloperidol or apomorphine and were sacrificed 90 and 45 min respectively after drug administration. Each value is the mean $\pm$ s.e.m. of the number of determinations indicated in parentheses. * P < 0.01; ** P < 0.001, ns (not significantly different), in respect to the values of the homolateral striatum of rats administered with saline. † P < 0.01, ††, not significantly different, in respect to the values of the homolateral striatum of rats administered with haloperidol alone.

Fig. 1 Photomicrographs ($\times 5.25$) of a cresylviolet-stained section from a rat injected unilaterally in the striatum with kainic acid (3 μ g) 10 d earlier. *a*, Control striatum; *b*, kainic-injected striatum.

striatum but increased by about 100% the levels of DOPAC in the lesioned striatum. Similar results were obtained after 0.5, 0.2 and 0.05 mg per kg of fluphenazine.

Apomorphine administration (0.5 and 0.1 mg per kg; s.c.) produced a more pronounced decrease of DOPAC in the kainic-injected than in the control side. Finally, as shown in Fig. 2, apomorphine (0.1 mg per kg), failed to decrease DOPAC levels both in the kainic-injected and in the control striatum of rats pretreated with haloperidol (0.3 mg per kg). On the other hand, a higher dose of apomorphine (0.5 mg per kg) partly reversed the increase in DOPAC produced by haloperidol (0.3 mg per kg) in the lesioned and in the control striatum.

The complete loss of striatal DA-sensitive adenylate cyclase does not prevent the effect of DA-receptor blockers, as haloperidol and fluphenazine, and of a DA-receptor agonist, as apomorphine, on DA-metabolism. Since haloperidol and apomorphine were mutually antagonistic, their effects on DOPAC in the kainic-injected striatum should be mediated by an action on DA-receptors. Taking the loss of striatal DA-sensitive adenylate cyclase as demonstrating destruction of postsynaptic DA-receptors¹⁰, our results indicate that an action at the level of the postsynaptic DA-receptors is not a pre-requisite for the *in vivo* effects of DA-receptor blockers and agonists on DA-metabolism and strongly suggest the existence of an alternative dopaminergic mechanism exerting an inhibitory influence on DA-neurons.

The exact location of this mechanism remains to be established. It might be pre-junctional, being mediated by DA released from DA-terminals on to presynaptic DA-receptors regulating tyrosine hydroxylase^{15,16} and DA-release¹⁷ or located within the substantia nigra and mediated by DA released from dopaminergic dendrites on to DA-receptors localised on dopaminergic neurones⁶ or on connections afferent to the substantia nigra²¹.

A further interpretation of our data could be that the changes produced by the drugs in the kainic-injected striatum are mediated by an action on postsynaptic DA-receptors of non-striatal dopaminergic areas left intact by

the kainic treatment. This possibility is made unlikely, however, by the fact that the lesion produced by the intra-striatal injection of 3 μg of kainic acid was not restricted to the caudate-putamen but also involved other dopaminergic areas as the nucleus accumbens, the bed nucleus of the stria terminalis and the central nucleus of the amygdala. Prefrontal cortex was not found to be damaged but the paucity¹⁸ and uncertainty¹⁹ of the cortical afferences to the substantia nigra makes it difficult to admit that this area mediates the changes observed on the kainic-injected striatum. The tuberculum olfactorium was not affected by kainic acid but nigral afferences from this area have not been described¹⁸. Finally, the finding that the sensitivity of striatal DA-metabolism to neuroleptics and apomorphine is increased in spite of the large loss of brain DA-receptors produced by kainic acid is difficult to be interpreted as due to the activity of a residual extra-striatal negative feedback loop.

Note added in proof: A paper from Garcia-Munoz *et al.*²² has recently appeared, in which a different approach was used to reach the same conclusions of the present one.

Hydroxyproline-containing protein adsorbed on to cellular elements of whole human blood

CURRENT hypotheses suggest that blood clotting occurs when, as a primary event, platelets come into direct contact with collagenous fibrils which have been exposed in vessel walls. We report here that a collagen component is normally associated with the cellular elements of blood. It was demonstrated by analysing whole blood and its fractions for protein-bound hydroxyproline, and shown by immunofluorescence in clotted blood smears using a specific antiserum to human collagen. As a blood component it is distinct from and additional to Clq, the hydroxyproline-containing protein which is a part of the first component of complement.

Hydroxyproline was first measured in serum and plasma by LeRoy¹ and was believed to be related to a soluble collagen component of blood. It was later found that this hydroxyproline was more probably related to Clq, which shares amino acid sequences including hydroxyproline, with collagen^{2,3}. The total serum concentration of hydroxyproline attributable to Clq, assuming a concentration of Clq in serum of 180 $\mu\text{g ml}^{-1}$ (ref. 4) and a hydroxyproline content of 5.4%, is 9.7 $\mu\text{g ml}^{-1}$ (ref. 5). Recent studies of whole citrated blood have shown about double this amount of hydroxyproline to be present, that is, 18 $\mu\text{g ml}^{-1}$ (ref. 6). The discrepancy between the serum and whole blood concentrations of hydroxyproline is apparently entirely due to collagen, which is all bound to blood cells.

Blood was drawn from three women (ages 25-52 yr) and three men (ages 23-67 yr) and hydroxyproline measured by the method of Woessner⁷ in whole blood, plasma and serum (Table 1). In agreement with the literature, plasma (or serum) has less than 10 $\mu\text{g ml}^{-1}$ bound hydroxyproline, so that the additional 10 $\mu\text{g ml}^{-1}$ originates from proteins

Table 1 Hydroxyproline levels in whole human blood and blood fractions

bound or adsorbed on to cellular elements. This was also seen in direct analyses of centrifuged cells, hydrolysed *in toto*, and in determinations of plasma plus cell washings. (For washing, 1 ml of 0.9% NaCl was added to 1 ml of whole blood; this is mixed and centrifuged and the supernatant removed. The cellular precipitate was resuspended in 1 ml 0.9% NaCl, recentrifuged, and the supernatant was again removed. This was repeated three times. Hydroxyproline determinations were performed on the pooled supernatants.)

To ascertain whether this adsorbed hydroxyproline-containing protein represented a form of collagen or Clq, prepared antiserum to human collagen (collagen D, Fig. 1) was used^{8,9}. The antiserum was adsorbed with whole human plasma and then used to visualise collagen in blood smears and clots by immunofluorescence using the indirect method. Smears and sectioned clots were prepared without the use of anticoagulants. The preparations were treated with anticollagen antiserum followed by fluorescein conjugated goat anti-rabbit serum⁸.

In the clots, a prominent diffuse reticulum of fluorescent fibrils interlaced the cellular masses (Fig. 2c,e). The smears showed highly fluorescent platelets and platelets aggregated (Fig. 2a). The clotted extremities of the smear showed a brilliant, if delicate, version of the sectioned clot (Fig. 2b). Here platelet clumps could be distinguished at every fibrillar intersection and could represent the points of initiation for a collagen fibrillar component of clot formation. There was a faint fluorescence surrounding red blood cells which cannot yet be unambiguously attributed to collagen. Collagenase (Worthington) removed the fluorescence reaction from fibrils and platelet clumps (Fig. 2d). Sections were subjected to additional controls including blocking, pretreatment with control rabbit sera, and pre-adsorption of the anti-human collagen serum with the

Fig. 1 Fractionation of human achilles tendon.

collagen antigen. Following these steps, the fluorescence reaction for collagen was negative.

The human collagen antiserum was extensively evaluated for specificity. After adsorption with plasma it did not react with serum proteins nor with C1q (M.B.E., unpublished). Amino acid analysis of collagen D was similar, although not identical, to that for human skin collagen¹⁰.

Fig. 2 Immunofluorescence smear and clot preparations of normal human blood stained by the indirect method using a rabbit anti-human collagen serum and a goat anti-rabbit serum conjugated with fluorescein isocyanate. *a*, Blood smear showing platelet fluorescence. At arrow, fine threads of an incipient clot. *b*, Clotted portion of blood smear showing additional collagen component possibly radiating from platelet foci. *c* and *e*, Collagen staining of sectioned clots with maximal appearance of collagen reactive material. *d*, Collagenase control of sectioned clot. Scale bars, 10 μ m.

We had attempted to remove, as far as possible, serum protein contaminants from this preparation. There was evidence for the presence of an unusual post-histidine residue corresponding to the histidinohydroxymerodesmosine described in other insoluble forms of collagen¹¹. It is not known whether the antiserum distinguishes between fibrillar and monomeric collagen.

Isolation procedures to characterise the hydroxyproline-containing protein of blood have been begun by one of us (R.M. and Bezkorovainy, A.). Plasma and supernatants of washed cells were applied to a Sepharose 6B column, using H₂O as eluting medium. Two hydroxyproline-containing peaks were resolved, one appearing in the void volume (molecular weight 10⁶), the other at a molecular weight of 400,000. The eluting medium was changed to 0.1 M NaHCO₃ and two hydroxyproline peaks again appeared, at molecular weights of 400,00 and 300,000. We assume that the 400,000 peak is C1q, while the large protein is some form of collagen which dissociated when the buffer was changed.

The interaction of collagen with platelets *in vitro* has been extensively studied¹²⁻¹⁵, always, however, with the assumption that the *in vivo* source of collagen was subendothelial tissue exposed by vascular injury. The presence of a collagen-like protein already present on the cellular surface must modify this interpretation. Addition of aggregating agents to platelets in platelet-rich plasma showed an almost immediate involvement of amorphous surface material in interplatelet bonds¹⁶. These bonds strongly resemble those seen in Fig. 2*b*. Not only platelets, but leukocytes and erythrocytes interact and aggregate with fibrillar collagen *in vitro*¹⁷. The binding sites involved in this collagen interaction—at least in the platelet and possibly in the leukocyte—also bind C1q and in its presence collagen-induced aggregation is lost. There thus seems to be competition of collagen and C1q for the same binding sites¹⁸⁻²².

In early stages of clotting, a substantial collagen reaction is present on platelets, but a portion remains occult, appearing as insoluble highly reactive fibrils only in areas where clotting had begun and showing maximally in the sectioned clot. Thus an intriguing question is whether this part of the circulating collagen is normally associated with the erythrocyte surface and becomes reactive during clotting. We have not examined smears from anticoagulated blood by immunofluorescence.

The hydroxyproline-containing protein described here

resembles collagen in both antigenic and chemical qualities and is a physiological component of the formed elements of blood. As such, it is certainly involved in their interactions including clot initiation and the possible displacement of Clq from antigen-antibody complexes. This role, and its modifications in situations where collagen becomes abnormally mobilised from tissues, remains to be evaluated in the areas of blood sedimentation, clotting, haemostasis and thrombosis.

We thank L. Butikas and N. Iwaniw for technical assistance and I. Stoncius for photographic preparations. Dr Henry Gewurz provided a gift of Clq. This work was supported by the US PHS and by a grant from the Pearl S. Stetler Foundation to R.M.

Effect of a single amino acid substitution on stability of conformation of a protein

THE role of individual amino acid residues in stabilising protein molecules is of interest, especially in connection with the mechanism of thermoresistance of thermophilic bacteria¹ and in connection with the physicochemical basis of temperature sensitive mutants used widely in molecular biology studies. This problem has been approached mainly with the use of synthetic polypeptide², chemical modification of natural proteins³, or homologous proteins⁴⁻⁹ from different species. Many mutants of microorganisms are available from genetic studies, however, in which the mutant proteins differ from wild type only at a single amino acid position. Such proteins often differ markedly in stability. We describe here a study of the α -subunit of tryptophan synthetase of *Escherichia coli*. The data suggest that the stability of a protein may be highly correlated with the hydrophobicity of the amino acid residues at some suitable positions. Further studies of this type may clarify the role of individual amino acid residues in stabilising proteins.

Many mutants of *E. coli* producing an α -subunit of tryptophan synthetase with a single amino acid substitution have been isolated¹⁰, and α -subunits of tryptophan synthetase from some *E. coli* mutants have altered stability¹¹. Table 1 shows a comparison of heat inactivation of tryptophan synthetase α -subunits from mutant and wild-type strains. Marked effects were seen when Glu

at position 49 was replaced by Gln (strain *trpA11*) or by Met (*trpA33*); the α -subunit became more labile or more stable, respectively. These results confirm those reported by Maling and Yanofsky¹¹.

α -Subunits were purified from the wild-type strain and the mutant *trpA33*, respectively, using the method of Creighton and Yanofsky¹² with a slight modification. Purified samples gave a single band on polyacrylamide gel electrophoresis. Circular dichroism (CD) spectra (200-250 nm) of the purified α -subunits from the wild type and *trpA33* were mutually not distinguishable and coincided with the results of Heyn and Weisheit¹³ on the wild-type protein. The heat inactivation of the purified samples coincided with those of crude extracts. We can therefore assume that the difference in thermostability of crude enzymes in Table 1 reflects the difference in that of the α -subunit molecule itself, which

Table 1 Heat inactivation of α -subunit of tryptophan synthetase of *E. coli*

Cells suspended in pH 8.0, 0.1 M Tris-HCl buffer were disrupted in a Branson Sonifier B-12 sonic oscillator. The supernatant solutions obtained by centrifugation for 2.5 h at 80,000g were used for the heat inactivation study. These mutant proteins are inactive in the conversion of indole-3-glycerolphosphate to tryptophan, but retain the activity for the conversion of indole to tryptophan in the presence of pyridoxal phosphate, serine, and β -subunit of tryptophan synthetase of *E. coli*¹⁴. This latter activity was measured by the disappearance of indole after reaction at 37 °C for 20 min¹⁴. The β -subunit was extracted from mutant strain *trpA2* of *E. coli*. Heat treatment was done for 20 min at 58 °C.

is due to replacement of a single amino acid residue. The conformational changes of the α -subunits on heating were examined by measuring the CD values at 222 nm, where the CD spectra of the α -subunits showed a large negative Cotton effect. After incubation for 60 min at 60 °C in pH 8.0, 0.1 M Tris-HCl buffer, the per cent of remaining ellipticity at 222 nm of α -subunits from the wild type and *trpA33* was 66.5 and 82.0% respectively. After cooling for 10 min at 25 °C, the ellipticity of α -subunits from the wild type and *trpA33* recovered to 81.5 and 94.0%, respectively. When 0.2 mM dithioerythritol was present in the sample solutions, changes of ellipticity on denaturation were similar to those seen in its absence, but the recovery of the ellipticity was stimulated remarkably in both wild-type and mutant proteins. These results show that the conformation of the α -subunit from *trpA33* is more stable to heat than that of the wild type. It must be pointed out that the activity of α -subunit may recover to some extent during assay (20 min at 37 °C) after heat treatment. Data on heat inactivation of enzymatic activity may therefore only partially reflect conformational stability of the α -subunit.

We examined urea denaturation of the two proteins as an indication of stability, and also as the simplest procedure¹⁵ for estimating the free energy change of unfolding. Figure 1 shows a comparison of urea denaturation of the purified α -subunits of the wild type and the mutant *trpA33* measured by the change in CD at 222 nm. The mutant *trpA33* protein was more resistant to urea than that of the wild type, corresponding to the relative stabilities on heat denaturation. From far-ultraviolet CD spectra, the two proteins could be considered to be completely denatured in 8 M urea. The denatured proteins were renatured by diluting (Fig. 1),

Fig. 1 Urea denaturation of the α -subunits of the wild type (Δ , $\blacktriangle$) and the mutant *trpA33* ($\circ$, $\bullet$). Temperature 25 °C, pH 8.0, 0.025 M Tris-HCl buffer. The solution contained 0.1 mM EDTA and 0.2 mM dithioerythritol. Open symbols represent the ellipticity at 222 nm after incubation for 60 min in urea solutions at various concentrations. Filled symbols represent the measurement of the samples diluted after exposure to 8 M urea solution to demonstrate the reversibility of the denaturation. CD measurements were carried out with a Jasco J-20 recording spectropolarimeter.

and enzymatic activity recovered completely. Urea denaturation is thus reversible in these conditions. The midpoints of urea denaturation curves at 25 °C were 3.1 and 3.9 M urea for the wild type and the mutant *trpA33*, respectively.

We analysed the data shown in Fig. 1 assuming that the urea denaturation can be approximately represented by an equilibrium between a unique native form and a completely unfolded form^{8,9,15}. Figure 2 shows the dependence of the free energy change of unfolding on the urea concentration. By extrapolating to zero concentration, the free energy changes of unfolding in water for the α -subunit of the wild type and the mutant *trpA33* are calculated to be 2,290 and 3,040 cal mol⁻¹, respectively. The difference between the wild type and the mutant *trpA33*, 750 cal mol⁻¹, amounts to about 30% of the free energy change of unfolding for the wild type.

X-ray diffraction studies have shown that the replacement of Glu 49 by Met caused little alteration of the conformation of the α -subunit¹⁶. Our results, taken together with the above data, show that a single amino acid substitution increased the stability of the molecule without a gross change in conformation. The side chain contribution of an amino acid to free energy change for transfer from ethanol to water has been estimated to be 1,300 and 550 cal mol⁻¹ for Met and Glu, respectively¹⁷. The difference between them, 750 cal mol⁻¹, coincides with the difference of the free energy change of unfolding of the wild type and the mutant *trpA33* proteins obtained here. This suggests that the increase in stability

Fig. 2 Effect of urea concentration on the free energy change of unfolding for α -subunits of the wild type (Δ) and the mutant *trpA33* ($\circ$). ΔG for two-state transition is given by the following equation; $\Delta G = -RT \ln K$. An equilibrium constant, K = (concentration of unfolded molecule)/(concentration of native one), is calculated from the data shown in Fig. 1, using only those points where K is between 0.2 and 5.0 (ref. 15). The lines in the figures were calculated by the method of least squares.

of the mutant *trpA33* protein compared with the wild type might be accounted for by the difference of hydrophobicity of Glu and Met, if we assume that the position 49 is somehow buried in the hydrophobic interior of the molecule. Although hydrophilic residues such as glutamic acid are usually located on the surface of protein molecules, there are exceptions, especially when the residues are in the active sites of enzymes¹⁸. In the case of Glu 49 of the α -subunit of tryptophan synthetase, its substitution by Met results in loss of activity with indole glycerolphosphate and serine as substrate, though not with indole and serine¹⁴. We may therefore assume that it is in the active site of the enzyme and hence in a largely hydrophobic interior environment, which may be simulated by ethanol or similar solvents, and in which partners for hydrogen bonding are at hand.

Our results suggest that the stability of an enzyme may be greatly increased by the increase in hydrophobicity by substitution of a few suitable amino acid residues. Stability of enzymes from thermophiles could be explained by similar mechanism.

We thank Drs K. Hamaguchi, T. Takagi, Y. Kyogoku and H. Ozeki for their valuable comments. Drs C. Yanofsky, I. P. Crawford and S. Hiraga provided mutant *E. coli* strains.

Preponderance of synonymous changes as evidence for the neutral theory of molecular evolution

ACCORDING to the neutral mutation-random drift hypothesis of molecular evolution and polymorphism^{1,2}, most mutant substitutions detected through comparative studies of homologous proteins (and the nucleotide sequences) are the results of random fixation of selectively neutral or nearly neutral mutations. This is in sharp contrast to the orthodox neo-Darwinian view that practically all mutant substitutions occurring within species in the course of evolution are caused by positive Darwinian selection³⁻⁵. This paper shows that by comparative studies of messenger RNA (mRNA) sequences reliable estimates can be obtained of the evolutionary rates (in terms of mutant substitutions) at the third positions of the codon, and that the estimates conform remarkably well with the framework of the neutral theory.

Salser *et al.*⁶ have presented a comparison of homologous parts from the fragments of the human and rabbit haemoglobin mRNA sequences. Among 53 nucleotide positions that can be compared, there are six base differences, of which only one leads to amino acid difference. Their Table 5 shows that among 17 third nucleotide positions of the codon which can be compared

between the two species, there are 5 nucleotide differences. To estimate the number of nucleotide substitutions per site (K) that have occurred in the course of evolution since the divergence of the rabbit and human lineages, I use the following formula which converts the observed difference into the estimate of evolutionary divergence

$$K = -\frac{3}{4} \log_e(1 - 4/3 \lambda) \quad (1)$$

In this formula, λ is the observed fraction of the sites by which two homologous sequences differ from each other (for details, see ref. 7); K includes superimposed and reverted mutant substitutions. The rate of nucleotide substitution per site per year can then be obtained by $k_{\text{nuc}} = K/(2T)$, where T is the time (yr) since the divergence of the two lineages. Also, the standard error (σ_K) of K may be computed using a formula given in ref. 7. Letting $\lambda = 5/17$ in equation (1), we obtain $K = 0.373$. The corresponding standard error (σ_K) is 0.182. Thus, taking $T = 8 \times 10^7$, we obtain $k_{\text{nuc}} = (2.3 \pm 1.1) \times 10^{-9}$ (the present estimate should be statistically more reliable than the corresponding estimate given in ref. 6). This is a very high evolutionary rate, comparable with that of the fibrinopeptides. If we denote by k_{aa} the rate of amino acid substitutions per site, it is known that for fibrinopeptides $k_{\text{aa}} = (4 \sim 9) \times 10^{-9}$ (see refs 8, 9). This figure, when converted into the nucleotide substitution rate, is $k_{\text{nuc}} = (1.8 \sim 4.0) \times 10^{-9}$. In addition, a direct comparison of human and rabbit fibrinopeptide A (using data given in ref. 8) gives $k_{\text{aa}} = 5.2 \times 10^{-9}$ leading to $k_{\text{nuc}} = 2.3 \times 10^{-9}$.

A similar but more interesting report comes from Grunstein *et al.*¹⁰ who compared histone H4 (that is, histone IV) mRNA sequences of two sea urchin species *S. purpuratus* and *L. pictus*. It is well known that histone H4 is by far the most highly conserved protein (with $k_{\text{aa}} = 0.006 \times 10^{-9}$ (ref. 8)). Their report¹⁰ now shows, however, that many synonymous changes (that is, the changes that do not lead to amino acid changes) have occurred in the gene coding for this protein in the course of evolution. From their Table 3, showing 84 nucleotide sites that can be compared between the messenger sequences of the two species, there are ten base differences, of which nine are located at the third positions of the codon. Actually, there are 27 third nucleotide positions which can be compared between these two species and there are nine nucleotide differences. Thus, we obtain $K = 0.440$ and $\sigma_K = 0.163$. According to Grunstein *et al.*, these sea urchins shared a common ancestor approximately 6×10^7 yr ago. Therefore, letting $T = 6 \times 10^7$, we obtain $k_{\text{nuc}} = (3.7 \pm 1.4) \times 10^{-9}$ as an estimate of the average evolutionary rate at the third nucleotide position of the codon in the histone H4 gene. It is remarkable that, in this gene, synonymous mutant substitutions have occurred with the highest known rate, in spite of the fact that the amino acid substitutions have occurred in the corresponding protein with the lowest known rate.

How do these observations bear relation to the neutral theory? Let k be the rate by which mutant genes are substituted in the species in evolution. If a certain fraction f_0 of the molecular mutants are selectively neutral and the rest are definitely deleterious (assuming that definitely advantageous mutations are negligible in frequency), then for neutral alleles, the rate of mutant substitutions is equal to the mutation rate¹. Therefore

$$k = \nu_T f_0 \quad (2)$$

where ν_T is the total mutation rate. Now, among the prominent features¹¹ of molecular evolution the following two are particularly noteworthy: (1) for a given protein, the rate of evolution is roughly constant per year and (2) the molecules or parts of molecules that are subject to less functional constraints evolve (in terms of mutant substitutions) faster.

As to the first feature, the neutralists assume that for a given molecule f_0 is roughly constant. Recently, some authors, such as Fitch and Langley¹², have emphasised the non-constancy, but

their results show, in agreement with our earlier estimate¹³, that the variance of evolutionary rates among lines is only about 2.6 times as large as that expected from chance fluctuations. It is possible that there is delicate fluctuation of intrinsic evolutionary rate around the mean, as caused by shifting of the molecular constraint as amino acids are substituted one after another in various parts of the molecule. This means that the probability f_0 of a mutation being neutral is not strictly constant but fluctuates around its characteristic mean. Also, as pointed out by Ohta¹⁴, if nearly neutral but very slightly deleterious mutations are prevalent, the evolutionary rate fluctuates as the population goes through a series of bottlenecks. As to the difference of evolutionary rates among molecules or parts of molecules, the neutralists assume that the probability of a mutational change being neutral depends on functional constraints. Namely, the weaker the functional constraint, the larger the probability (f_0) of a random change being selectively neutral, with the result that k in equation (2) gets larger. According to this explanation, the maximum evolutionary rate is attained when $f_0 = 1$, that is, when all the mutations are neutral. Now, the high evolutionary rates observed at the third position of the codon can be explained from the neutral theory by assuming that the majority of synonymous changes are selectively neutral. Note that roughly 2/3 of random nucleotide substitutions at the third position of the codon are synonymous. The possibility of synonymous nucleotide changes being selectively neutral was discussed extensively in an early paper² on the neutral theory. Of course, it is possible that not all synonymous mutations are completely neutral, but the possibility is very high that, on average, synonymous changes are subject to natural selection very much less than the mis-sense mutations. On the other hand, if we adhere to the selectionist position that practically all the mutant substitutions in evolution are caused by positive natural selection, there can be no upper limit to the evolutionary rate at the molecular level (as directly set by the mutation rate ν_T), and there is no reason to believe that the rate of evolution is uniform even approximately for a given molecule among different species.

In my opinion, various observations suggest that as the functional constraint diminishes the rate of evolution converges to that of the synonymous substitutions. If this is valid, such a convergence (or plateauing) of molecular evolutionary rates will turn out to be strong supporting evidence for the neutral theory.

Inheritance of recombinant HLA-GLO haplotype suggesting the gene sequence

THE HLA region in man has been assigned to the short arm of chromosome 6 (ref. 1). Close genetic linkage has been shown between *HLA* and genes involved in the synthesis of the second^{2–3} and fourth⁴ components of complement as well as structural variation of the glycine-rich B-glycoprotein (GBG or Bf)⁵. Two enzymes, phosphoglucomutase-3 (PGM₃)^{6–7} and glyoxalase I (GLO)^{1,8–12}, and two blood group antigens, Chido¹³ and Rodgers¹, have been shown to be in this linkage group. Here we describe a

family with an intra-HLA recombinant sibling and an HLA-GLO recombinant sibling. The mother is heterozygous at the HLA-A and -B loci, homozygous for HLA-DW2, and heterozygous at the GLO locus, thus permitting identification of an HLA-GLO recombinant in one of her children. Our investigations suggest that the locus for GLO polymorphism is on the centromeric side of HLA-B on the short arm of chromosome 6.

Table 1 illustrates the family mixed lymphocyte culture results¹⁴ showing that the lymphocytes of the mother only weakly stimulated those of her children, but in the reciprocal MLC reactions, her lymphocytes responded briskly to their. The sero-identical siblings III and IV are non-responsive in mutual MLC reactions, indicating identity at HLA-D. Interestingly, sibling II shows low mutual MLC responses with the HLA-D identical siblings III and IV.

These observations were corroborated by the HLA-D typing (Table 2). The family members were tested against homozygous typing cells representing the HLA-DW1-4 clusters as defined by the Sixth International Histocompatibility Workshop 1975; two HTC (FS and KL) which do not fall within the presently defined DW clusters, and one HTC (JB-12) which corresponds to the specificity

LD 107. The HLA-D typing results were analysed by the relative response and cluster methods⁴. The mother types as a HLA-DW2 and seems to be homozygous. The siblings II, III and IV are HLA-D identical (DW1-DW2) and sibling I inherited an HLA-A to -B recombinant (HLA-DW2-LD-107).

Slightly higher MLC reactivity than one would expect with complete HLA-D identity is observed when sibling II serves as either stimulator or responder to the sero-identical siblings III and IV. Although all three siblings type as HLA-DW1, DW2, the maternal haplotypes apparently carry slightly dissimilar DW2 determinants. This interpretation is consistent with evidence previously presented that the HLA-D region is not governed by a single gene, but more probably by a group of closely linked genes. Thus, the respective maternal D determinants may be overlapping or one may represent an inclusion of the other determinant⁴. Alternatively, the two maternal haplotypes may carry the same major HLA-D determinants, but differ at minor determinants at another locus¹⁵ or may differ at response genes¹⁶. Furthermore, back stimulation may be present to minor HLA-D determinants¹⁷.

The Bf typing¹⁸ gives rise to three common phenotypes

Table 2 Chromosome 6—gene markers of M family

(SS, FS and FF) determined by the relative mobility of the slow or fast migration bands to the anode of the electrophoretic plate. The father and sibling I demonstrates the FS phenotype; the mother and siblings II, III and IV the SS phenotypes. Thus, the F component is linked to the HLA-AW29, B12 haplotype of the father. Since the mother is homozygous for the S determinant, the Bf typing is not informative in following the crossovers involving the maternal chromosomes in the recombinant siblings I and II.

Glyoxalase-1 (EC 4.4.1.5) catalyses the formation of S-lactoyl glutathione from glutathione and methylglyoxal. Genetic polymorphism of this enzyme in red blood cell lysates was first reported by Kompf, *et al.*¹⁹. They described three different starch gel patterns representing homozygosity and heterozygosity for two alleles, GLO¹ and GLO², with frequencies of about 0.40 and 0.60, respectively. The method of Kompf, *et al.*¹⁹ was used for this study, except a phosphate buffer was used²⁰. Since the enzyme is a dimer, the heterozygote pattern has three major zones (two homodimers and one heterodimer), while the homozygote patterns contain only one major band each. Thus, the phenotypes are unequivocal, even though they are difficult to photograph, because the sites of catalytic activity appear as a lighter shade on the surrounding darker blue background. Figure 1 shows the three common phenotypes.

Several investigators^{1,8-10} have reported genetic linkage of GLO and HLA on chromosome 6. Due to the inability to establish linkage between PGM₃ and GLO, Kompf¹¹ suggested that GLO might be located on the side of the HLA-D locus at a distance of about 15 map units. The

sex-dependent difference in recombination frequency noted by Lamm *et al.* for PGM₃ was not observed by Weitkamp *et al.*⁹ for GLO, an observation consistent with the postulation by Kompf¹¹ that GLO may be located in the HLA-A side of the chromosome. Subsequent family studies, however, show GLO segregates with HLA-B^{1,9-10}. Weitkamp *et al.*¹ in studies of linkage between HLA, Bf and GLO suggested the GLO is closer to Bf than to HLA. Meera Khan *et al.*¹ in other linkage studies suggested that GLO is situated between PGM₃ and HLA. Furthermore, from the estimated recombination frequency between HLA and GLO of 0.15 (ref. 8), Pretorius *et al.*¹⁰ postulated the GLO locus to be located outside of HLA-D.

Assuming the least number of recombinants in the family described herein, the GLO locus seems to be outside the locus for HLA-B. The placement of the GLO locus on the centromeric side of HLA-B is strengthened by the observation of MLC non-reactivity between siblings III and IV indicating their HLA-D identity. Thus, the maternal haplotypes are apparently HLA-AW32-B7-DW2-GLO2 and HLA-A2-BW21-DW2-GLO1. Sibling III inherited a recombinant haplotype HLA-A2-BW21-DW2-GLO2 with the recombination occurring somewhere between the HLA-B and GLO. Our investigation therefore suggests that the most probable order of loci on the short arm of chromosome 6 proceeding toward the centromere is: HLA-A, HLA-B, HLA-D, GLO.

Structure-function relationship of 5' non-coding sequence of rabbit α - and β -globin mRNA

RETICULOCYTES make essentially equimolar amounts of α - and β -globin as required for the correct assembly of haemoglobin. It has been shown, however, that α and β mRNAs differ in their rate constant for ribosome attachment^{1,2}. In particular α -globin mRNA initiates protein synthesis only 60% as frequently as β -globin mRNA (refs 3–5). The 5' non-coding region is thought to be involved in the binding of the mRNA to the ribosome for the correct initiation of protein synthesis. A comparative study of the sequences of the 5' non-coding regions of α - and β -globin mRNA may show whether their differential rate of initiation can be ascribed to specific features in the mRNA structure or whether it is a function of some other part of the translational machinery. Recently the complete sequence of the 5' non-coding region of rabbit β -globin mRNA has been elucidated⁶. I report here the complete sequence of the 5' non-coding region of rabbit α -globin mRNA, determined following essentially the same methodology.

A ³²P-labelled complementary DNA (cDNA) of the 5' non-coding region of both α - and β -globin mRNA was prepared using the synthetic deoxyhexanucleotide primer d(G-C-A-C-C-A) complementary to the codons for the Met-Val sequence common to both proteins and avian myeloblastosis virus (AMV) reverse transcriptase.

The cDNA was fractionated by one-dimensional homochromatography (see Fig. 1a). Bands 2, 3 and 5 were identified as cDNA of the 5' non-coding region of β -globin mRNA by their characteristic depurination fingerprints⁶. Bands 1 and 4 were tentatively classified as cDNA of the 5' non-coding region of α -globin mRNA because their intensity relative to the β bands increased when a template enriched in the α component

Fig. 1 *a*, Autoradiograph of a one-dimensional homochromatography fractionation of cDNA (ref. 7). Radioactive cDNA was prepared *in vitro* with AMV reverse transcriptase using each α -³²P-labelled deoxynucleoside triphosphate (dNTP) of high specific activity in turn and the other three unlabelled. The synthesis was carried out with all four dNTPs present (I), or in the absence of dATP (II). O denotes the origin, and the strong band at the top is unreacted dNTP. The reaction conditions were identical to those previously described⁶, except that the primer used was the hexanucleotide d(G-C-A-C-C-A) and the template was a mixture of α - and β -globin mRNA (a gift from Dr N. J. Proudfoot) obtained from the post-ribosomal supernatant that had been shown to be enriched in the α component⁸. AMV reverse transcriptase was a gift of Dr J. W. Beard. Bands 1 and 4 are cDNA of α -globin mRNA 5' non-coding region; band 1 ends before the first dA residue and band 4 is the full length copy. Bands 2 and 5 are cDNA of β -globin mRNA 5' non-coding region; band 2 ends before the first dA residue and band 5 is the full length copy. *b*, *c*, Two-dimensional fingerprints⁹ of a partial venom phosphodiesterase digest of band 1 labelled with dGTP (*b*) or dTTP (*c*). The sequence d(5') [T]G-G-T-G-G-T-T-C-C-T-T-C-T-C(3') was deduced from the relative mobilities of the intermediates. The absence of radioactive products after the last G shift in (*c*) is interpreted as the next residue being the dT adjacent to the primer.

Fig. 2 Gel analysis of partially minus reactions. Band 1 was eluted from the homochromatography⁷, desalted through a Sephadex G-100 column and freeze dried. The cDNA was then dissolved and re-annealed with mRNA. This preparation was divided into four aliquots, and 50 nM 'minus' reactions⁶ were performed. Each 'minus' mixture contained three dNTPs at 50 μ M concentration and one dNTP in turn (the limited one, so called 'minus') at 50 nM concentration. In this way it was possible to obtain from a single product (band 1) specific 'pile-ups' of radioactivity in positions corresponding to the limiting dNTP. The reaction mixtures were fractionated in 7 M urea 12% polyacrylamide gel. The slots marked -C, -A, -G, -T denote that the reaction analysed was carried out with the corresponding dNTP at a concentration of 50 nM. Slot O is a control lacking the enzyme. The bands correspond to positions in the sequence where the limiting dNTP is present. The numbering refers to the cDNA sequence shown in Fig. 3. Longer exposed films clearly showed bands at position 38–39 in the -A slot and at position 32 and 42 in the -G slot.

was used. Definitive evidence for this assignment is discussed below.

Nearest neighbour analysis carried out for band 1 showed that only when the label was α -³²P-dTTP was radioactive dAp found; dCTP and dGTP failed to label dAp (see Table 1). As band 1 was synthesised in the absence of dATP, and therefore lacked any internal dA residues, it was concluded that the last residue of the primer was the one labelled, as expected if the initiation codon was A-U-G. Depurination¹⁰ of bands 1 and 4 provided the data summarised in Table 1. Partial digestion with venom phosphodiesterase of the cDNA of band 1 was carried out; the two-dimensional fingerprint is shown in Fig. 1 *b* and *c*. The cDNA sequence d((5') G-G-T-G-G-T-T-C-C-T-T-C-T-C(3')) can be read off from the characteristic mobility shifts⁹. Note the sharp difference in spot intensity after the first G shift. This unusual pattern may be an indication of some structural feature (hairpin loop?) in this short cDNA oligonucleotide.

Combining data from depurination, nearest neighbour analysis and partial venom phosphodiesterase digestion, the sequence of band 1 cDNA was established as

To obtain the sequences between the end of band 1 and the end of band 4 (possibly the full length cDNA) a new gel sequencing technique was used¹⁹. This is an adaptation for RNA sequencing of the 'plus' and 'minus' system developed for Φ X DNA sequencing¹¹. It consists of the extension of a mixture, as heterogeneous as possible, of different transcript lengths in the complete absence of each one of the four dNTPs in turn. In this case a slight variation was introduced to overcome the problem

Table 1 Depurination and nearest neighbour analysis data from bands 1 and 4 cDNA (Fig. 1a)

Band no.	Input label	Base composition of depurination products (deduced from their position)	Nearest neighbour analysis data			
			C	A	G	T
1	dGTP	T[G]	0	0	1	1
1	dTTP	T ₂ C ₄ *, T	2	1	2	2
1	dCTP	T ₂ C ₄ *	1	0	0	3
4	dATP	C ₂ [A]; T ₂ C ₄ [A]*	—	—	—	—
4	dGTP	T[G]; T C[G]	—	—	—	—

Depurination data—5' and 3' terminal phosphates of depurination products are omitted. [] denotes that the base within brackets was deduced by nearest neighbour considerations. Thus depurination products obtained from α -³²P-dGTP or α -³²P-dATP input label oligonucleotides contain G or A residues respectively on their 3' sides. Nearest neighbour analysis—this section is divided into four columns indicating the products of analysis Cp, Ap, Gp and Tp. These are denoted by C A G T, respectively. Ratios of product yields were established by scintillation counting of the spots.

*Base composition deduced from the partial venom digests shown in Fig. 1b.

of nonspecific priming. The extension of a single product (the α -globin mRNA specific product—band 1) was carried out in partially minus conditions (each of the four dNTPs, in turn, at limiting concentrations—see Fig. 2). The band pattern produced allowed the reading of the cDNA sequence as d((5') A-G-T-C-G-G-A-C-T-G-G-A-C-C-A-X-A-A-X-T-G-T (3')) where X represents unknown residues, their presence deduced by the spacing of the bands. The last ten residues overlap with the sequences already reported for the 5' end of α -globin mRNA¹³, thus confirming the identity of the priming site. It is a ten-base overlap with two ambiguities. Because of the clear overlap it was not necessary to establish the nature of the

X residues in this study as they had been defined by others. The complete cDNA sequence deduced is shown in Fig. 3a.

The 5' non-coding regions of α - and β -globin mRNA (Fig. 3b) are substantially dissimilar in size and nucleotide composition. These sequences have only a few common features; residues 1–6 are identical¹³ and there is a purine-rich region centred six to eight residues to the left of the A–U–G initiating codon.

It has been suggested⁶ (although critical evidence is still lacking) that the region around the A–U–G initiating codon of β -globin mRNA and brome mosaic virus (BMV) RNA interact with the 3' terminal sequence of 18S rRNA. This is similar but not identical to the interaction between the 5' non-coding region of mRNA and 16S rRNA in bacteria^{14,15}. For α -globin mRNA the same interaction is possible at positions 37–41 (Fig. 3), involving the first two triplets of the coding region (common to both messengers) but forming one base pair less than β -globin mRNA. Another possible region of interaction with 18S rRNA is at nucleotides 8–12 (Fig. 3), but this is less attractive for two reasons. First, in the known bacterial examples¹⁵ the interaction of the mRNA with 16S rRNA occurs at a maximum distance of 10 bases from the initiation codon, while here if an interaction were to occur it would be 24 bases away. Second, it has been shown that the A–U–G is in a rather central position of the ribosome-protected fragment in the case of β -globin mRNA^{16,17}. It should be noted that residues 8–12 are in the stem of the proposed hairpin loop (see below).

An obvious problem with the proposed mRNA–18S rRNA interaction around the initiation codon is that both the Met-tRNA_i and the 18S rRNA would compete for the A–U–G sequence of the mRNA. This would be unlike the situation in *Escherichia coli* where the interacting site of the mRNA is displaced approximately ten nucleotides to the left of the initiation codon. The difficulty may be resolved if the two interactions occur sequentially rather than concurrently. Other parts of the extensive 5' non-coding region may also be involved

Fig. 3 a, Sequence of the cDNA. Numbers indicate the distance of the nucleotide at that position from the 5' end of the primer. The sequence between positions 34 and 43 has been previously reported¹³. b, Sequence of the 5' non-coding region of rabbit α - and β -globin mRNA. Numbers indicate the distance of the nucleotide at that position from the 5' m⁷Gppp structure. c, Base pairing of α - and β -globin mRNA with the known 3' end sequence¹³ of rabbit 18S rRNA.

Fig. 4 Possible conformation of the 5' non-coding region of α -globin mRNA. The estimated stability of the hairpin loop is discussed in the text. The underlined sequence is complementary to the 3' end of rabbit 18S rRNA (see Fig. 3).

in other RNA-RNA interactions; for example, by base pairing with internal positions of 18S rRNA.

A number of possible secondary structure models can be drawn by maximising the extent of base pairing. In particular for α -globin mRNA a hairpin loop can be constructed (Fig. 4) that has a large negative free energy (ΔG (25 °C) = -7.6 kcal), estimated according to the rules proposed by Tinoco *et al.*¹⁸. Other secondary structures can be drawn that partially 'mask' the postulated 18S rRNA interacting region (underlined in Fig. 4), but are less stable than the proposed loop. For β -globin mRNA there is no indication of stable secondary structure⁶. The best hairpin loop that can be drawn (not shown) has a negative free energy six times smaller than the α -globin mRNA conformation shown in Fig. 4 and is considered to be unstable, or only marginally stable. It is interesting to note that the α -globin mRNA hairpin loop (Fig. 4) involves about two-thirds of the 5' non-coding region, and most of the adjacent sequence is common with that of β -globin mRNA (the first six nucleotides and the first two codons, see Fig. 3).

The purpose of this study was to elucidate the sequence of the 5' non-coding region of α -globin mRNA. It was hoped that a comparison of this sequence with its β counterpart would provide a clue to understanding the molecular basis of their differential rates of initiation. The 5' non-coding regions of α and β -globin mRNA are 36 and 53 nucleotides long, respectively. They show few common features, making it difficult to pinpoint specific sequence differences that may be correlated with the differential rates of initiation. One significant point to arise, however, was that α -globin mRNA seemed to have a strong hairpin loop whereas β -globin mRNA did not. Thus a knowledge of the 5' non-coding sequence has not established the cause of the differential rate of initiation but has suggested that it might be caused by the differences in secondary structure.

I thank Dr G. G. Brownlee for advice and the British Council for a fellowship.

A new pathway for DNA repair in *Escherichia coli*

MOST studies on mutagenesis involve exposing a growing population of cells to a large dose of mutagen for a short period. In a natural environment, however, cells are probably exposed more often to a low concentration of mutagens for long periods. We therefore measured the accumulation of mutants in *Escherichia coli* cells growing continuously in the presence of very low concentrations of mutagens. Because many mutagens are highly unstable, it was necessary to devise a system in which cells could be continuously exposed to fresh mutagen. To do this we took advantage of the fact that certain bacteria can grow and divide while attached to the underside of a Millipore filter. This system was originally developed by Helmstetter and Cummings¹ as a means of producing synchronous cells, because as growth medium is passed through the filter it carries away with it the unattached daughter from each pair of newly divided cells. The mutagen to be studied can therefore be stored in stable conditions and only mixed with the growth medium immediately before being passed through the filter; for example the mutagen *N*-methyl-*N'*-nitro-nitrosoguanidine (MNNG) can be stored in citrate buffer at pH 5.0 in which it has a half life of 40 h compared with 2.3 h in synthetic minimal media^{2,3}. We had intended to determine the relationship between ambient concentration of various mutagens and resulting mutation rate. The first mutagen studied was MNNG and the results were totally unexpected.

Fig. 1 The effect of previous growth in 1 $\mu\text{g ml}^{-1}$ MNNG on mutagenesis and killing by a short exposure to 100 $\mu\text{g ml}^{-1}$ MNNG. *E. coli* F26 (B/r., *thy his*) was grown at 37 °C with aeration to a density of 1×10^8 cells per ml in M63 medium⁴ supplemented with glucose (0.1% w/v), thymine (4 $\mu\text{g ml}^{-1}$) and histidine (40 $\mu\text{g ml}^{-1}$). At -1.5 h, MNNG (1 $\mu\text{g ml}^{-1}$) was added and samples were removed every 15 min till time zero; during this period the viable count increased 2.3-fold. At time zero, the culture was filtered and resuspended in the absence of MNNG, after which samples were removed every 30 min for a further 4 h. MNNG (100 $\mu\text{g ml}^{-1}$) was added to each sample for 5 min and the samples were then filtered, diluted and plated on nutrient broth plates and on M9 (ref. 7) plates containing thymine but not histidine. Survival (○) and *his*⁺ reversion (●) were measured. (The transient drop in survival of cells at time zero, indicated by interrupted lines, is apparently due to a transient increased susceptibility of cells to MNNG immediately after filtration.)

Bacteria on a filter could be kept growing for at least a week in a continuously replenished supply of medium containing $1 \mu\text{g ml}^{-1}$ fresh MNNG, and this produced a significant increase in frequency of reversion of a *his* nonsense mutation. The mutations arose only during the first hour of exposure to MNNG, however, and no further increase in frequency could be detected during the remaining 4–7 d of the experiment. (The technical details of these long term experiments will be published elsewhere and are not relevant here.) A similar result had been reported by Jiménez-Sánchez and Cerdá-Olmedo³ but they were more interested in where the mutations arose in the chromosome than in when they appeared during MNNG treatment, and so did not pursue the matter further. The simplest interpretation for our failure to collect an increasing number of mutants with time would be that the constant exposure to MNNG allows each bacterium to handle MNNG more efficiently and so become resistant to MNNG mutagenesis. Here we show that bacteria can indeed quickly become resistant to MNNG, apparently through the induction of a novel form of DNA repair.

The first and simplest experiment was to add $1 \mu\text{g ml}^{-1}$ MNNG to an exponentially growing liquid culture of *E. coli*. At various times thereafter samples from the culture were subjected to $100 \mu\text{g ml}^{-1}$ MNNG for 5 min and the resulting number of mutants and extent of killing were measured. The results clearly indicate that the bacteria had become increasingly difficult both to kill and to mutate during their growth in $1 \mu\text{g ml}^{-1}$ MNNG. On removal of the MNNG from the growing culture these properties decayed over a period of 4 h (Fig. 1). This effect looks very much like the induction and decay of a gene product and indeed, as Fig. 2 shows, the attainment of MNNG resistance did not occur in the presence of chloramphenicol and hence requires *de novo* protein synthesis.

Although we have not carried out any very extensive study of other mutagens, preliminary experiments have shown that a low level of MNNG induces resistance not only to MNNG itself but also to *N*-methyl-*N*-nitrosourea and ethyl methanesulphonate; it does not, however, induce resistance to ultraviolet light or methyl methanesulphonate.

The chloramphenicol-sensitive step that brings resistance to MNNG could be the synthesis of a protein which operates in one of two ways. The protein could prevent lesions being formed in the cells, for example, by making

Fig. 2 The effect of chloramphenicol on the induction of MNNG resistance. At time zero MNNG ($1 \mu\text{g ml}^{-1}$) was added to two cultures of *E. coli* F26. Samples were removed every 20 min and challenged with $100 \mu\text{g ml}^{-1}$ MNNG for 5 min, and the number of induced mutations was measured. One culture received chloramphenicol ($100 \mu\text{g ml}^{-1}$) for the first 20 min (○) and the other did not (●). A control experiment had previously shown that such exposure to chloramphenicol had, on its own, no effect on the response to challenge with MNNG.

the cell impermeable to MNNG or by breaking down MNNG as it enters the cell; or it could allow cells to handle the lesions more efficiently, for example, by carrying out some form of DNA repair like the inducible SOS repair system described by Witkin⁴ and George *et al.*⁵

All the available evidence seems to suggest that the effect is due to the induction of a new pathway for DNA repair, and is not due to something that prevents lesions being formed. For example, preliminary experiments have shown that methylation of DNA by ³H-MNNG occurs at approximately the same rate in induced and non-induced cells (P. Jeggo, personal communication). In addition, the survival of transforming plasmid DNA (ref. 8) that has been alkylated by MNNG *in vitro* is greater if it is assayed in cells that have been induced by MNNG (Fig. 3). Thus the

Fig. 3 The ability of transforming DNA, previously alkylated by MNNG *in vitro*, to transform induced and non-induced *E. coli* C803. MNNG was added to samples of tetracycline-resistant (Tet^r) PMB9 DNA (ref. 8) to 0.1, 1 and 10 mg ml⁻¹ at 37 °C for 25 min, and subsequently removed by dialysis overnight. These DNA samples were used to transform competent *E. coli* C803 cells (*gal*⁻, *met*⁻, *supII*⁻, *hsr*⁻, *hsm*⁻, *supIII*⁺) which were either induced (○) or non-induced (●) by 1 h of growth in $1 \mu\text{g ml}^{-1}$ MNNG. The efficiency of transformation was measured by the number of Tet^r transformants produced when competent cells were transformed by $1 \mu\text{g ml}^{-1}$ DNA.

function of the induced protein(s) is probably to repair damage caused by the mutagen. But, unlike the SOS repair system^{4,6} which allows increased survival at the cost of an increased mutation rate, this system lowers the mutation rate; further, preliminary experiments have shown that it involves a different set of gene products than SOS repair (P. Schendel, personal communication). We therefore believe that these results indicate the presence in *E. coli* of a DNA repair system, which is inducible but relatively error-free.

We thank Jeffrey Williams for help with the transformation experiment.

Wide ranging plasmid bearing the *Pseudomonas aeruginosa* tryptophan synthase genes

THE wide ranging group of plasmids comprising the P compatibility class in *Escherichia coli* (ref. 1) (the P-1 class in *Pseudomonas aeruginosa* (ref. 2)) contains within it some members capable of serving as sex factors for the transmission of chromosomal markers from one *P. aeruginosa* strain to another. Haas and Holloway³ selected variants of one such P-1 plasmid, R68, that had become highly efficient in *Pseudomonas* chromosomal gene mobilisation. Some of these variants are also efficient sex factors in *E. coli* and *Rhizobium leguminosarum*⁴. Previous work with P-1 plasmids showed that they can incorporate resistance markers from *Pseudomonas*-specific plasmids and transmit them to *E. coli*⁵. We report here the analogous incorporation of the chromosomal *trpAB* genes from *P. aeruginosa* into R68.44, and a study of the expression of these genes after transfer to *E. coli* K12.

The tryptophan synthetic pathway and the genes responsible for its several steps in *E. coli* and *P. aeruginosa* are shown in Fig. 1. In *Pseudomonas* the two genes encoding the α and β chains of tryptophan synthase, *trpA* and *trpB*, are widely separated from the remaining pathway genes; this gene pair is regulated through induction by the substrate, indoleglycerol phosphate, rather than repression by L-tryptophan as is the case for certain other *Pseudomonas* *trp* genes and the entire *E. coli* *trp* operon⁷. Genetic studies^{8,9} have suggested that this regulation is autogenous and that the *trpA* gene product is at least part of the repressor, but a direct test of this hypothesis has been impossible because of the lack of a suitable source of DNA bearing the *Pseudomonas* *trpAB* region.

PAC174, a strain of *P. aeruginosa* requiring lysine and carrying the plasmid R68.44, was grown in nutrient broth

Fig. 1 Pathway of tryptophan (Trp) synthesis from chorismate (Chor). Intermediates: anthranilate (Anth), phosphoribosyl anthranilate (PRA), 1-o-carboxyphenylaminodeoxyribulose-5-phosphate (CDRP), indole-3-glycerol phosphate (InGP) and indole (Ind)[enzyme-bound]. Above the reactions the genes of the tryptophan operon of *E. coli* are drawn, arrows indicating the reactions their protein products participate in. Locations of the three *trp* mutations in strain IC762 are shown, along with the deletions ($\Delta trpE1417$ and $\Delta tonBtrpA201$) present in a double deletion strain in which a set of plasmid variants similar to those in Table 1 were also obtained. Because of poorer growth yields associated with the *tonB* character, enzymic analysis was performed only in the IC762 background. Below the reactions are shown the chromosomal *trp* gene distributions for *P. putida* and *P. aeruginosa*. (The location of the *trpG* gene is deduced from indirect evidence, since mutations affecting its gene product have not yet been reported.) Arrows indicate the reactions each gene produces catalyses.

together with *E. coli* W3110 resistant to rifampicin and carrying *trpA33*, a non-reverting mutation which produces an ineffective tryptophan synthase α chain¹⁰. After incubation at 37 °C for 3 d, the mixture was plated on minimal lactose agar with 50 $\mu\text{g ml}^{-1}$ of rifampicin. About one cell in 10^{10} formed a colony. All seemed indistinguishable and one clone, designated W3110*trpA33rif*^R (*ptrpAB*), was chosen for study.

It was a typical *E. coli* K12 with the antibiotic resistances and phage sensitivities characteristic of a strain carrying R68.44 (ref. 3). When R751 (ref. 11), a plasmid incompatible with R68.44, was introduced into W3110*trpA33rif*^R (*ptrpAB*), the drug resistances and the ability to grow without added tryptophan were lost. When *ptrpAB* was transferred to *E. coli* K12 strains carrying various *trp*⁻ mutations, it conferred prototrophy on those strains with defective *trpA* or *B* genes or with an extensive deletion involving these genes (Fig. 1) but not on those with mutations in *trpC*, *D*, or *E*.

Measurement of the molecular weight of covalently closed circular (CCC) plasmid DNA by sedimentation through a neutral sucrose gradient gave a value of 37.6×10^6 for R68.44 and 113×10^6 for *ptrpAB*. Thus, *ptrpAB* seems to carry at least 75×10^6 of DNA from the *P. aeruginosa* chromosome. Since the molecular weight of entire *P. aeruginosa* chromosome is about $2,100 \times 10^6$ (ref. 12), *ptrpAB* carries about 3.6% of it. *ptrpAB* is unstable; plasmid species conferring resistance to ampicillin, tetracycline and kanamycin and sensitivity to phages specific to P plasmids, but not containing the *trpAB* genes, can be transferred from *E. coli* (*ptrpAB*). Neutral sucrose gradient analysis of ³H-labelled *ptrpAB* CCC DNA (Fig. 2) shows,

Fig. 2 Neutral sucrose gradient analysis of *ptrpAB* DNA. Covalently closed circular tertiary DNA forms of ³H-labelled *ptrpAB* and ¹⁴C-labelled R68.44 were isolated using caesium chloride-ethidium bromide density gradient centrifugation¹⁶. A mixture of the two plasmid DNAs was analysed by sedimentation through a 4.6-ml 5-20% sucrose gradient¹⁷ for 70 min at 100,000g and 20 °C. Fractions (0.1 ml) were collected directly on to glass fibre disks and, after drying, washing and redrying, were assayed for radioactivity. Sedimentation was from right to left. O, ³H; ●, ¹⁴C. The molecular weights of the plasmid species were calculated as described¹⁷.

in addition to CCC DNA of molecular weight 111×10^6 (fraction 15), a CCC DNA species of molecular weight similar to the CCC DNA of ¹⁴C-labelled R68.44 (fraction 28). The ¹⁴C-DNA peak at fraction 34 is open circular DNA of R68.44 formed by spontaneous single-strand scission of the CCC DNA. The ³H-DNA co-sedimenting with this peak probably represents the open circular form of the smaller DNA species found in *ptrpAB* DNA.

To study the expression of the plasmid-borne *trpA* and *trpB* genes we transferred *ptrpAB* into *E. coli* IC762, a derivative of W3110 that is *his*⁻, *str*^R, and bears three

mutations in the *trp* operon, *trpE3* (a mis-sense mutation inactivating the first tryptophan-specific enzyme), *trpB248* and *trpA2* (mis-sense and ochre mutation affecting the β and α subunits of tryptophan synthase, respectively). The intact *trpD* and *trpC* genes in this triple mutant allow anthranilate taken up from the medium to be converted to indoleglycerol phosphate, but no further along the pathway (Fig. 1). IC762 cells containing *ptrpAB* have the expected antibiotic resistance complement and require histidine and tryptophan. When provided with anthranilate in place of tryptophan they grow very slowly (>10 h generation time), although their copious excretion of ferric chloride-positive material indicates that availability of indoleglycerol phosphate cannot be limiting the growth rate. Extracts of cells grown in the presence of anthranilate have extremely low tryptophan synthase activity (Table 1). (For comparison, *P. aeruginosa* PAC21, the plasmid-free parent of PAC174 and hence donor of the *trp* genes on *ptrpAB*, grown in minimal medium has 0.70 tryptophan synthase units per mg protein.)

Table 1 Tryptophan synthase levels in cells harbouring R68.44 *ptrpAB* plasmids

Strain	Tryptophan	Culture conditions Anthranilate	Indole
IC762	< 0.02	No growth	No growth
IC762 (<i>ptrpAB</i>)	< 0.02	0.0	No growth
IC762 (<i>ptrpAB-1</i>)	< 0.02	0.70	No growth
IC762 (<i>ptrpAB-2</i>)	0.02	1.42	No growth
IC762 (<i>ptrpAB-3</i>)	2.57	2.09	2.07
IC762 (<i>ptrpAB-4</i>)	0.08	0.83*	0.72

Strain IC762 is an F⁻*his^rstr^r* derivative of the triple mutant *trpE3 trpB248 trpA2* constructed and characterised earlier¹⁴. Plasmid-bearing cells were grown 16–20 h at 37 °C with shaking in 1 l of minimal medium¹⁵ containing 0.2% glucose, 0.05% acid hydrolysed casein, and 4 mg of tryptophan or 10 mg of anthranilate or indole. Reversion controls showed the strains' growth properties to be unchanged at the time of collection. Cells were centrifuged, washed once in 0.1 M potassium phosphate, pH 7.5, suspended in 5 ml of the same buffer and disrupted by sonication. Extracts were assayed for tryptophan synthase (indole → tryptophan) and protein as described^{7,8}. Specific activity is given in units (0.1 μ mol per 20 min) per mg protein.

*This culture also contained 4 mg of tryptophan because the cells cannot grow on anthranilate alone.

We have not succeeded in isolating single-step variants of IC762 (*ptrpAB*) able to grow rapidly on anthranilate. After several serial transfers of 10-ml cultures in minimal medium containing anthranilate in place of tryptophan, however, we obtained a succession of faster growing strains whose improvements were plasmid-associated. Table 1 presents enzyme assays of two members of such a series, *ptrpAB-1* and *ptrpAB-2*. Growth rates conferred by these plasmids on several *E. coli* strains lacking tryptophan synthase are about proportional to the enzyme levels; that of IC762 (*ptrpAB-2*) growing on anthranilate is approximately 4 h. Enzyme levels are quite low in cells grown in the absence of anthranilate (Table 1) and the level of enzyme induced by anthranilate is not influenced by excess tryptophan (data not shown).

Strains lacking anthranilate synthase and having *ptrpAB* as their sole source of tryptophan synthase do not grow at all on low levels (5 μ g ml⁻¹) of indole in place of tryptophan. Even those containing *ptrpAB-2* do poorly (generation time >12 h). In this they resemble anthranilate synthase-less mutants of *P. putida*⁷ and *P. aeruginosa*¹³. We sought mutants of IC762 (*ptrpAB*) able to utilise indole at this concentration, for the *Pseudomonas* precedent^{7,8} suggests that such mutants may either be constitutive for tryptophan synthase or have mutations in *trpA* abolishing the ability to grow on anthranilate but permitting indole to act

as an inducer. Indole utilisers of both types were found (Table 1). In each case the regulatory change was shown to be plasmid-associated when the extrachromosomal element was transferred to other *E. coli* strains.

The tryptophan synthase produced by *ptrpAB-1*, *ptrpAB-2* and the regulatory mutants *ptrpAB-3* and *ptrpAB-4* was found to resemble that of *P. putida* and *P. aeruginosa* in its response to monovalent cations^{7,13} and was effectively neutralised by antiserum prepared to the β_2 subunit of the *P. putida* enzyme but poorly by antiserum to the *E. coli* β_2 subunit. One millilitre of antiserum against the β_2 subunit of *P. putida* tryptophan synthase neutralises 18 units of *ptrpAB-2* enzyme produced in IC762 or the double deletion background, and 36 units of PAC21 tryptophan synthase. Antiserum against *E. coli* β_2 subunit (homologous neutralisation 1,430 units ml⁻¹) gave only 4 units ml⁻¹ neutralisation against the plasmid-derived or the PAC21 enzyme. Clearly enzyme produced in *E. coli* by the plasmid genes is very similar to that of the *P. aeruginosa* parent, though more precise characterisation awaits its availability in greater quantity and purity.

We conclude that *ptrpAB* contains, in addition to the genes of R68.44, a rather large segment of the *P. aeruginosa* chromosome including the *trpAB* gene pair. The regulation of this gene pair in *E. coli* cytoplasm seems to be similar to that in *Pseudomonas* rather than the coliforms. Any gene products other than tryptophan synthase required for this regulation must be present on the 75 $\times 10^6$ segment of presumably contiguous chromosomal DNA carried by the plasmid. As first isolated, the plasmid's *trpAB* gene activity was low. Variants were found having more normal activity levels. The nature of these variants is not clear, but the existence of an impediment to the expression of certain *Pseudomonas* genes in *Escherichia* ought to be borne in mind when intergeneric recombinant DNA experiments are contemplated.

A.E.J. is supported by a grant from the Medical Research Council of the United Kingdom and I.P.C. by a grant from the National Institutes of Health. We thank Janet Cresswell (London) and Elizabeth McLeod and Barbara Wang (La Jolla) for assistance. Bruce Holloway, Pat Clarke and Charles Yanofsky gave us bacterial strains and valued advice.

Phonons and the elastic moduli of collagen and muscle

BIOLOGICAL fibres make a suitable subject for the development of the science of biomaterials. The amino-acid sequence of the collagen molecule is known^{1,2}, and has been used to account for the self-assembly of collagen into native fibrils¹ and polymorphic forms³, the pattern of bands due to positive staining in electron micrographs⁴ and the low-angle meridional X-ray diffraction pattern⁵. The collagen structure to amino acid resolution in axial projection is thus completely understood. Here we relate this structural picture to the mechanical properties (and since we are dealing with a biological fibre, these are also the biological properties) of the fibres. This can be done by investigating the vibrational and other motions of the molecular assembly in collagen. The force constants of hydrogen bonds in some polypeptides have been estimated on the basis of models⁶ but no experimental measure of their magnitude has been reported. We describe measurements of the inelastic light scattering (Brillouin) spectra of collagen from rat tail tendon from which we obtain elastic moduli of the tropocollagen molecule and an estimate of hydrogen bond force constants. We have also studied effects of hydration on the spectra to obtain information about the association of water with collagen in the native state. For comparison we have made preliminary measurements on molluscan 'catch' muscle in which the polypeptide conformation is different from collagen.

Samples of collagen were excised from tail tendons of adult rats and a bundle of fibrils ~0.2 mm in diameter mounted under tension sufficient to remove the characteristic banded appearance under the polarising microscope and produce alignment of the fibrils. The Brillouin spectra were recorded using a triple-pass Fabry-Perot interferometer (based on Burleigh Instruments model DAS-1/RC140) and were excited using between 5–50 mW of argon laser light at 514.5 or 488.0 nm. The incident and scattered beams were in the horizontal plane at 90° to one another and the sample orientated at 45° to these directions such that momentum transfer was along the fibre axis. In this configuration the wavevector transfer to the sample is independent of its refractive index and is equal to $2\sqrt{2}|k_0|$ where k is the wavevector of the laser light *in vacuo*.

Figure 1 shows spectra of a sample mounted in air at 12% relative humidity at 25 °C. There is a central feature due to elastically scattered light at the laser frequency and two inelastic components due to energy gain and energy loss. The

Fig. 1 Brillouin spectra for rat tail collagen fibres at 25 °C and 12% relative humidity showing the mode polarisation.

Fig. 2 Brillouin spectra from the air-dried anterior byssus retractor muscle of *Mytilus edulis* (at 25 °C) at two values of the relative orientation of the fibre and the scattered momentum transfer, q . Upper trace, q // fibre axis; lower trace, q 10° off axis.

frequency shift of these components varies linearly with laser frequency indicating that they correspond to acoustic phonons. The spectra in Fig. 1 are for two different polarisations of the incident and scattered light; VV refers to both polarisations vertical, that is, perpendicular to the scattering plane, and VH refers to incident polarisation vertical and scattered polarisation horizontal. The Brillouin components are of order 40-times stronger in VV than in VH polarisation; we can thus identify the scattering as due to longitudinal acoustic waves propagating parallel to the fibre axis⁷. No transverse acoustic modes have been observed at frequency shifts greater than 6.0 GHz despite an extensive search.

Figure 2 shows spectra from the anterior byssus retractor muscle of *Mytilus edulis*. The specimen had been dried in air at 25 °C and was mounted in the same manner as the dry collagen sample. Only one side of the elastic peak is shown; in the upper spectrum the sample is at exactly 45° to the incident laser beam and, by coincidence, Stokes and anti-Stokes Brillouin components from adjacent orders of interference overlap. In the lower spectrum the sample is tilted 20° towards k_0 such that wavevector transfer is about 10° from the fibre axis and the two Brillouin components are then just resolved because of the anisotropy in the acoustic velocity.

Figure 3 shows spectra for samples of collagen in 0.15 M NaCl solution; collagen in air at 100% relative humidity and for pure water in an equivalent scattering geometry. The measurement in 0.15 M NaCl was made with the fibre orientated as before but pressed between microscope slides, thereby ensuring that the fibre was bathed continually in the solution by capillary action. This arrangement prevents drying and gives the closest approach to the native condition of the collagen fibre (A. M. and B. B. Doyle, unpublished). For the measurement at 100% relative humidity the fibre was mounted in a cell at 25 °C through which humidified air was circulated for 2 d before the measurements started.

Figure 4 illustrates the result of experiments in which the collagen fibre was held in air at 25 °C at various relative humidities. The frequency of the longitudinal acoustic mode decreases as the humidity is increased and for high humidities approaches the frequency observed in 0.15 M NaCl (compare upper two spectra in Fig. 3). The intensity scales were different for each spectrum. In fact the Brillouin intensity is more or less unchanged over the whole range of humidities. The peak widths were instrumental. Spectra at different humidities were difficult to reproduce for two reasons. First, local heating by the laser beam dried the sample locally and thus the observed frequencies were power dependent; the spectra of Fig. 4 were obtained

Fig. 3 Brillouin spectra from collagen *a* in 0.15 M NaCl solution between slides and *b* in 100% relative humidity vapour compared with *c*, the Brillouin spectrum of water. Brillouin scattering is from rat tail collagen laser heating effects.

using the lowest possible laser power (~ 5 mW) but even so at 84% and 100% humidity are appreciably affected by local drying, as can be seen by reference to Fig. 3. Second, hysteresis in the hydration of the fibres was observed; the frequency depended on whether a previously dried fibre was humidified or a wet fibre dried to a particular humidity. Experiments were performed to see if the Brillouin frequency of 84% humidity depended on external load attached to the fibre. The frequency was the same, within experimental error, for tensions between 1×10^7 and 4×10^8 dyn cm^{-2} .

Table 1 gives the measured longitudinal mode frequencies, corresponding acoustic velocities and elastic moduli, in various conditions. The calculation of elastic modulus requires knowledge of the density of the material. For dry collagen and muscle we estimate the density ρ from the excluded volumes of different amino acid residues present⁸ and their masses. For dry collagen $\rho = 1.43$ g cm^{-3} and for muscle $\rho = 1.40$ g cm^{-3} .

In the native state, assumed to be at 95% humidity, $\rho = 1.16$ g cm^{-3} (ref. 1) (assuming density of water = 1) for collagen. The amount of water present was taken from the adsorption isotherms for collagen¹⁰.

To discuss the sound velocities and moduli in collagen and muscle we take as a basis the calculations of Fanconi and Peticolas⁶ on poly-L-alanine. The paramyosin chain of the muscle, where the α helix is gently supercoiled with a second molecule, 3.5 residues per turn (1.485 Å repeat distance) as opposed to 3.6 in the α helix (1.5 Å repeat distance), is closely related to this synthetic α -helical polymer. The acoustic slope of the seven mass model poly-L-alanine can be fitted to the observed frequency and the calculated wavevector when one chooses a hydrogen bond force constant of about 0.07 m dyn $\text{\AA}^{-1}$. For synthetic macromolecules¹¹ the modulus decreases strongly with degree of coiling because bond twisting rather than bond stretching or angle opening strains accommodate the stress. This is presumably also the case for the polypeptide and so this hydrogen bonding force constant must, for the moment, be regarded as a fitting parameter. By the same principles, the higher modulus of collagen compared with muscle is consistent with the collagen conformation being more extended (3.3 residues per turn and 2.86 Å between residues). The moduli obtained by light scattering are about two orders of magnitude stiffer than the values derived from static measurements involving macroscopic extensions. This is again a familiar observation for synthetic polymers¹¹ and indicates inhomogeneous strain for measurements.

The sound velocity in collagen decreases monotonically with the degree of hydration (Table 1). Since the bulk density decreases on hydration it is supposed that both softening of the intrachain forces, particularly the hydrogen bonds, and rigid loading of the chains by the adsorbed water occurs. At 85% humidity there is about one water molecule adsorbed per peptide on the average¹⁰. At this point the mass per unit length of the chain has increased by 35% giving a frequency decrease of 17% compared with the 32% actually found. The decrease can be parameterised by first accounting for the decrease in sound velocity due to rigid loading, and then estimating the changes in H-bond force constant by interpolating the reduced sound velocities between values derived from the seven atom model calculations of Fanconi and Peticolas⁶ with a range of assumed H-bond force constants. This procedure gives the figures in the last column of Table 1. This approach is preferred to a discussion involving changes in the molecular conformation as a result of hydration since there is no detectable change in the high-angle X-ray diffraction pattern. At very high hydration the approach used here breaks down and the effects may be discussed using extended hydrodynamics¹².

In summary, measurements of the inelastic light scattering

Table 1 Acoustic properties of collagen and muscle at 25 °C

Substance	Q ($\text{\AA}^{-1}$)	v (GHz)	Sound velocity (cm s ⁻¹)	Density (g cm ⁻³)	Elastic modulus (dyn cm ⁻²)	H-bond force constant (m dyn $\text{\AA}^{-1}$)

from collagen and muscle give values for the velocities of acoustic waves and elastic moduli in the medium. For dry collagen this leads to an estimate of the hydrogen bond strength. For material in the native state the measurements are capable of giving information about the dynamics of water molecules in the material.

Crystal structure of anhydrous cholesterol

CHOLESTEROL, the most abundant steroid in the animal kingdom, is found mainly as a component in cell membranes and lipoproteins. The presence of the hydrophilic C(3) hydroxyl group in this otherwise hydrophobic molecule allows cholesterol to occupy a position at polar-nonpolar interfaces. Crystals of 3-hydroxy steroids and their hydrates show a tendency towards double layer structures with an end-for-end arrangement of approximately parallel molecules¹. As this molecular organisation is generally similar to that in membranes, it can be expected that some of the principles of intermolecular association in membranes might be revealed in the molecular packing in the crystal structures. Another common feature in these structures is the presence of more than one molecule in the crystallographic asymmetric unit. While this is a complicating factor in structure analysis, it clearly increases the amount of information regarding preferred conformation and intermolecular association to be gained from a structure determination. Craven² has recently reported the remarkable crystal structure of one form of cholesterol monohydrate. The arrangement of the eight crystallographically independent molecules in the triclinic cell shows unusual local pseudo-symmetry. One pair of molecules is related to another by a non-crystallographic $b/2$ translation, while a third pair, oriented end-for-end relative to the first, is related to the fourth by a similar $a/2$ translation. Non-crystallographic twofold rotation symmetry relates members of the first and the third pairs. The overall structure is a stacking of bilayers of 33.9 Å total thickness. We report here that anhydrous cholesterol crystals are also triclinic, with eight independent molecules per cell. This structure offers additional insight into the packing of cholesterol molecules, and a comparison with the monohydrate structure.

Colourless lath-shaped crystals were obtained by cooling a saturated acetone solution of cholesterol. The cell dimensions are $a=14.172(7)$, $b=34.209(18)$, $c=10.481(5)$ Å, $\alpha=94.64(4)$, $\beta=90.67(4)$ and $\gamma=96.32(4)^\circ$, in agreement with values reported by Bernal *et al.*¹, and converted to a reduced cell³: $a=14.00$, $b=33.71$, $c=10.46$ Å, $\alpha=94.5^\circ$, $\beta=90.0^\circ$ and $\gamma=95.9^\circ$. Since cholesterol is an optically active compound, the space group of the triclinic crystals is $P1$. Each unit cell contains eight $C_{27}H_{46}O$ molecules; thus there are 224 non-hydrogen atoms per asymmetric unit. The calculated density is 1.021 g cm^{-3} ; the experimental value (floatation) is 1.03 g cm^{-3} . A total of 10,399 unique reflections were measured to the limit $2\theta(\text{CuK}\alpha)=100^\circ$ using a Syntex PI diffractometer with a graphite monochromator.

The structure was solved by a combination of vector search methods⁴ and direct methods⁵. Vectors representing the known geometry of the rigid 21-atom 3-hydroxy steroid group were used in Patterson-space orientation searches which gave several probable orientations of this group in the crystal. Vectors between steroid groups in these orientations were used in translation searches. In this way it was possible to position three oriented steroid groups in relation to each other in such a way that searches with the three sets of inter-group vectors gave a consistent result. This 63-atom partial structure was used to calculate input

Fig. 1 The crystal structure of anhydrous cholesterol viewed along c (out of page). The upper figure is to be superposed on the lower one to give the complete structure. Two unit cells ($x = 0-1$; $y = 0-2$) are shown, displaying non-crystallographic twofold symmetry axes at $x \approx 0.5$; $y \approx 0.5, 1.0$ and 1.5 . Atoms are shown as 50% probability thermal motion spheres. Oxygen atoms shaded.

phases to the MULTAN programme³, modified to hold selected input phases fixed throughout the phase extension and refinement. The structure then emerged in a straightforward manner. About 80% of the hydrogen atoms were found in difference Fouriers, including those eight which are involved in hydrogen bonding. Refinement by block-diagonal least squares, with anisotropic C and O thermal parameters, gave $R=0.056$ for 8032 reflections with $I > 2.33\sigma(I)$.

There are no significant differences between the steroid skeletons of the eight molecules in this structure, the

average atom-atom misfit in superposing steroid skeletons being 0.07 Å. The conformation of the tail part of the cholesterol molecule shows considerable variation, however, as shown in Fig. 1, where molecules A and C represent two extreme cases in their C(17)–C(25) distances of 6.60 and 5.51 Å, respectively. This variability in the hydrocarbon chains is less pronounced in the monohydrate² where the chains are partially folded to an approximately equal degree.

The hydrogen bonding pattern (Fig. 2) consists of two independent chains of hydrogen bonds running parallel to

Fig. 2 The structure viewed along a (into page). Two unit cells ($y = 0-2$; $z = 0-1$) are shown, as in Fig. 1. The dashed lines indicate hydrogen bonding.

c with an average O...O distance of 2.87 Å. The hydrogen bond chains are staggered by ± 2.18 Å about a mean plane parallel to *ac*. This corrugated sheet of separated, parallel chains is to be compared to the pleated sheet of hydrogen bonds in the monohydrate.

The steroid planes of the eight molecules show no tendency towards parallel packing. The dihedral angles between least-squares planes of adjacent molecules range from 3° to 88°. The long molecular axes, while generally oriented along *b*, show considerable variation in direction. The angles between the least-squares lines calculated from any two molecules range from 4° to 36°. This is in contrast to the monohydrate, in which all the ring systems are approximately parallel and aligned.

Careful examination of the adjacent unit cells (Fig. 1) reveals an approximate local symmetry axis at $x=0.5$, $y=1.0$ along a direction making angles of 90.0, 94.5 and 0.7° with the crystal axes *a*, *b* and *c*, respectively. A 180°

Fig. 3 Schematic representation of the non-crystallographic symmetry in four adjacent cells. The left- and right-leaning question marks represent, respectively, the molecular clusters ABCD and EFGH. Local symmetry elements shown are co-axial twofold rotation and screw axes at $y=1$ and a 'twofold screw axis' with alternating translational components of 0.25 and 0.75 *c* at $y=0.5$ and 1.5. This diagram applies at $x=0$ and 0.5.

rotation about this axis brings the leftmost molecules A, B, C and D into close coincidence with the molecules E, F, G and H of the adjacent (right hand) cell. The mean atom-atom misfit between the 112 atoms of the first four molecules, turned as a rigid group, and the second 112 atoms is only 0.24 Å. This fit is as good in the C(17) chain regions as it is in the steroid skeleton regions. The remaining molecules E, F, G, H of the left hand cell are related to A, B, C, D of the right hand cell by a pseudo-twofold screw axis which is coaxial with the pseudo-twofold rotation axis. Figure 3 illustrates in diagrammatic fashion the relationships among the molecules of four adjacent unit cells. Non-crystallographic symmetry axes can also be seen to exist at $x=0.5$, $y=0.5$ and 1.5 in Fig 3. These are 'screw axes' whose translation components alternate between (very nearly) $c/4$ and $3c/4$, instead of the usual one-half cell translation.

With the presence of this pseudo-symmetry, the non-crystallographic asymmetric unit contains four molecules. These four 'unique' molecules are A, B, C and D. As can be seen in Fig. 2, there is no hydrogen bonding between these molecules. It seems that this unique structural unit is held together primarily by hydrophobic interactions.

The number of 'unique' molecules, that is, molecules not related to each other by either local or strict symmetry,

is the same in the monohydrate² and the anhydrous form. The nature of the non-crystallographic symmetry in the two structures is entirely different; there is no non-crystallographic half-cell translation in the anhydrous structure. Yet, in each case, the non-crystallographic symmetry is obeyed locally to a remarkably high degree.

Direct evidence for an interaction of β -adrenergic blockers with the 5-HT receptor

ADVANCES in neurotransmitter receptor identification and quantification by biochemical techniques involving radio-labelled analogues of putative neurotransmitters have led to the characterisation of a number of receptor systems in mammalian brain tissue¹; these include the catecholamines^{2,3}, 5-HT⁴, glycine⁵ and GABA⁶ receptors. The development of these techniques has provided a means of screening chemical compounds for their effects on different receptor systems⁷. The central nervous system effects of ($\pm$)-propranolol (Inderal, ICI) in animals are well documented^{8,9}. This drug has therapeutic benefit in man in anxiety¹⁰, and is also reported to have similar benefit in schizophrenia^{11,12}, essential tremor¹³ and drug dependence¹⁴. The origin of these effects is not understood but theories about its mode of action include β -adrenergic blockade¹⁵, membrane stabilisation⁸ and a 5-HT receptor blocking action^{16,17}. We report here that propranolol a stereospecific affinity for the 5-HT receptor from rat brain which is similar in magnitude to the putative 5-HT receptor blocking drug methylsergide.

Specific binding of ³H-5-HT was measured by the method of Bennett and Snyder⁴. The whole brain (minus the cerebellum) of a freshly killed Alderley Park rat (250-350 g) was rapidly removed and homogenised in 30 ml of ice-cold 0.32 M sucrose with five passes of an air-driven glass-Teflon homogeniser. After centrifugation at 1,000g for 10 min, the supernatant was subjected to 17,000g for 30 min to obtain a crude mitochondrial pellet. The pellet was lysed with 30 ml of ice-cold distilled water and briefly homogenised as before. The lysate was then spun at 10,000g for 20 min. The pellet from this spin, a bilayer with a soft, buffy upper layer was washed carefully to collect the upper layer and the resultant supernatant centrifuged at 48,000g for 20 min. The pellet was suspended in 6 ml of 75 mM Tris-HCl buffer (pH 7.4) containing 25 mM MgCl₂·6H₂O and 50 μ g ml⁻¹ of nialamide.

Incubations (15 or 16.5 min, 37 °C) were carried out in glass test tubes in a 1 ml final volume containing 75 mM Tris-HCl (pH 7.4), 25 mM MgCl₂·6H₂O, 5 nM ³H-5-HT (specific activity 14 Ci mmol⁻¹, Radiochemical Centre, Amersham), 640-840 μ g of protein, the appropriate concentration of the drug under test and in the presence or absence

of 10^{-6} M 5-HT. Incubations were terminated by filtration under reduced pressure through Whatman GF/C filter papers. The filtration procedure consisted of quenching the incubation with 4 ml of ice-cold buffer, rapid filtration, followed by two further washes with 4 ml of buffer. The complete washing procedure usually took less than 10 s. The residual radioactivity on the filter papers was counted at 31% efficiency in a PCS scintillant (Amersham-Searle). Protein was estimated by the method of Lowry *et al.*¹⁸. 'Nonspecific' binding, defined as the radioactivity left on the filter paper in the presence of 10^{-6} M 5-HT, was subtracted from total binding in each experiment to give 'specific' or receptor binding. Specific binding at 5 nM ³H-5HT was in the range 55–65% of total binding.

In accord with Bennett and Snyder⁴, we have shown that the specific portion of ³H-5-HT binding is rapid, reversible, saturable and of high affinity ($K_D = 11.7 \pm 2.5 \times 10^{-8}$ M, average of three experiments, $\pm$ s.e.m.). The concentration at which specific ³H-5-HT binding is inhibited by 50% (IC_{50}) by the two putative 5-HT blocking drugs, methysergide and cyproheptadine, are given in Table 1 and are close to the previously reported values⁴. Also shown in Table 1 are IC_{50} values for the 5-HT receptor of a number of β -

5-HT receptor reported here is in accord with these findings. The significance of these observations in relation to the effects of propranolol in the central nervous system of animals and man remains to be evaluated.

Table 1 Effects of various drugs on ³H-5-HT binding to crude synaptic membranes

Drug	Half maximal inhibition of specific ³ H-5-HT binding (M)
5-HT	$1.7 \pm 0.3 \times 10^{-8}$
Methysergide	$2.8 \pm 0.3 \times 10^{-7}$
Cyproheptadine	$4.8 \pm 1.1 \times 10^{-8}$
(-)-Propranolol	$2.1 \pm 0.4 \times 10^{-7}$
(+)-Propranolol	$1.2 \pm 0.2 \times 10^{-8}$
(±)-Propranolol	$6.0 \pm 1.2 \times 10^{-7}$
(±)-Alprenolol	$3.0 \pm 0.5 \times 10^{-7}$
(±)-Oxprenolol	$4.3 \pm 0.8 \times 10^{-7}$
(±)-Pindolol	$7.9 \pm 0.8 \times 10^{-7}$
(±)-Practolol	$> 10^{-4}$
(±)-Atenolol	$> 10^{-4}$

³H-5-HT binding was assayed as described in the text. Results are means $\pm$ s.e.m. of triplicate determinations from at least three separate experiments using six different concentrations of the drugs indicated. The concentration of the drug giving half maximal inhibition of specific ³H-5-HT binding was determined by log probit analysis.

adrenergic blocking drugs. Propranolol has a substantial affinity for the 5-HT binding site, indeed (-)-propranolol is equipotent with the 5-HT blocking drug, methysergide, in displacing ³H-5-HT from its receptor. The interaction of propranolol with the 5-HT receptor is stereospecific as is evidenced by an approximately 58-fold lower affinity of the isomer (+)-propranolol, the racemate drug (±)-propranolol is about half as potent as the (-)-isomer alone. Other β -adrenergic blocking agents also have substantial affinity for the 5-HT receptor (Table) although β -blockers which are cardioselective *in vivo*, for example practolol and atenolol, have IC_{50} 's greater than 10^{-4} M.

Thus, we have demonstrated a stereospecific interaction of propranolol and other β -blockers with the 5-HT receptor, an action which was previously unknown for this class of drug. It seems that the affinity of β -blockers for the 5-HT receptor does not necessarily parallel their β -blocking potency in tissues outside the central nervous system since pindolol, an extremely potent β -blocker, is less potent in displacing ³H-5-HT than (-)-propranolol. Green and Grahame-Smith¹⁷ have suggested, on the basis of the blocking action of (-)-propranolol on a L-tryptophan induced hyperactivity syndrome in rats, that this drug inhibits central 5-HT function. The direct interaction of propranolol with

In the article 'Nucleosynthesis and anomalous xenon and krypton in carbonaceous chondrites' by J. B. Blake and D. N. Schramm, *Nature* **263**, 787, the references on the following sentences with proper reference numbers should have read: Perhaps the explanation of the anomalous light isotopes lies in either the p-process^{8,10} or in fractionation⁷. If the light xenon component is due to the p-process then ¹³⁰Xe might be affected, which would change the normalisation⁹.

reviews

Birth of a Universe

John Barrow

The First Three Minutes. By Steven Weinberg. Pp. 188. (Basic Books: New York, March 1977; Andre Deutsch: London, September 1977.) \$8.95; £4.50.

DURING the twentieth century, cosmology has been transformed from metaphysics to physics, creating one of the most exciting arenas for scientific investigation. The fundamental laws of physics on the one hand and dramatic progress in observational astronomy on the other make it possible to reconstruct a general evolutionary picture of the Universe's past history with some certainty.

If one takes the present structure and reverses the sense of the observed expansion then extrapolation backwards in time reveals increasingly denser and hotter cosmic epochs. The times of important event strata can be established in the manner of geology until eventually a 'big bang' is envisaged 10,000 Myr ago. This hot scenario for cosmogeny is based on the existence of a cosmic background radiation field, predicted by Gamow in 1948, and detected at microwave-lengths by Penzias and Wilson in 1964. The photons of this radiation background are now unanimously interpreted as a vestigial remnant of the extreme conditions prevailing in the primordial fireball itself, when matter was completely ionised and the Universe a high energy physicist's paradise.

The increasing temperature as we move further into the past towards the 'bang' ensures that cosmology can provide a remarkable theoretical laboratory for particle physics. Of particular importance has been the realisation that during the first few minutes of expansion from the 'bang', physical conditions were expedient for the fusion of light nuclei having distinctive abundances. The fossilised abundances of helium and deuterium have been detected in precisely the range predicted by the simplest models and reassure us that a view into the early opaque phase of the Universe's life is possible by indirect means. The contingency of thermodynamic equilibrium in the first few seconds washes away all the uncertainties surrounding the initial state and enables laboratory physics to develop a fairly complete description of events.

Steven Weinberg has again very successfully turned his attention from the world of microphysics, where his contributions are well known, to cosmology. *The First Three Minutes* is a clear and challenging description of the Universe's early evolution suitable for the informed layman and practising scientist alike. The author has vividly explained the essential concepts and physical processes involved, without recourse to mathematics or the details of general relativity, by introducing the necessary physical ideas as his story unfolds. One of the remarkable features of the book is the manner in which the author has maintained the rigour of his physical argument throughout, never sacrificing logical continuity in the interests of speed or oversimplification.

The first three chapters are partially historical in content, describing the discoveries of the universal expansion and microwave background radiation. Unfortunately, no explanation of the crushing blow dealt to the steady-state theory by the latter observations is provided. Such a description is essential in a work intended for the non-specialist, who often believes this theory still to be in strong competition with the 'big bang' cosmologies.

In the fourth chapter the physics of black-body radiation is described with great clarity, together with the conserved quantities necessary to specify the microstructure of the Universe uniquely. This careful build-up prepares the reader for the key chapter in which the phenomena peculiar to the first three minutes of expansion from the origin are expounded frame by frame. The final chapter is an ex-

cursion into the history of science in an effort to discover the reasons for scientists' procrastination in establishing this picture when the necessary observational and theoretical ingredients were apparently available.

Criticisms of the book are minor. Perhaps a little more space could have been allocated to the first three minutes rather than the past fifty years. The opportunity could then have been taken to mention Hawking's exciting work on primordial black holes or problems surrounding the existence of a singularity in spacetime. Some more clear diagrams displaying the evolutionary phases considered and their generic phenomena would also have been welcome landmarks to establish the overall panorama more vividly. Finally, a little more space might have been devoted to the conceptual problems associated with the standard model; these latter are of great intrinsic interest and motivate much current work in cosmology. Weinberg more than atones, however, for these failings with many fascinating digressions into points of basic physics and by a lucidity that makes for compelling reading. The provision of a glossary of technical terms, detailed index and bibliography are further attractive features of what will surely become a landmark in the exposition of the subject.

This book can be strongly recommended to all as the place to begin or reinforce their education in 'pre-historic' cosmology. □

John Barrow is a Junior Research Lecturer at Christ Church College, and a member of the Department of Astrophysics at the University of Oxford, UK.

Nerve, synapse and muscle

Electrobiology of Nerve, Synapse and Muscle. Edited by J. P. Reuben, D. P. Purpura, M. V. L. Bennett and E. R. Kandel. (Raven: New York, 1976.) \$30.

WRITTEN by his students and associates, this *Festschrift* volume in honour of Harry Grundfest contains a collection of recent studies on nerve, synapse and muscle. As might be expected from Grundfest's own interests, this volume ranges widely and provides fascinating glimpses of the ways in which an im-

portant area of biology has grown and developed. The chapters are uniformly interesting and no electrobiologist could pick up this book and fail to learn something new. Cell physiologists around the world will be delighted that Harry Grundfest's contribution has been honoured in this way.

P. F. Baker

P. F. Baker is Professor of Physiology at King's College, University of London, UK.

Mammalian cell membranes

Mammalian Cell Membranes. Vol. 2: The Diversity of Membranes. Vol. 3: Surface Membranes of Specific Cell Types. Edited by G. A. Jamieson and D. M. Robinson. (Butterworths: London and Boston, Massachusetts, 1977.) £18 each volume.

THESE two volumes continue an extensive coverage of the structure and function of cell membranes under the general editorship of G. A. Jamieson and D. M. Robinson. As in the first volume of the series, the editors adopt a relaxed attitude towards the form and content of each contribution, with the inevitable results of an uneven mixture of styles and a considerable amount of overlap in content. Nevertheless, a considerable amount of enjoyment is to be had from these books.

In the opening chapter of volume 2, Emmelot provides an excellent short account of the composition and organisation of the plasma membrane. His discussion of the interactions of the plasma membrane with microtubules and microfilaments, one of the growth areas in present-day membrane research, is particularly useful and includes a reminder that some of the initial effects of various drugs disrupting cytoplasmic contractile elements may be directly on the plasma membrane. Kramer and his colleagues then present a personal and very interesting account of membrane flow, the migration of components from the membranes of the endoplasmic reticulum to other membranes including the plasma membrane.

These two rather general reviews are followed by short chapters concerned, respectively, with membranes of the Golgi apparatus (Favard), mitochondria (Capaldi), lysosomes (Wattiaux), microbodies or peroxisomes (Tolbert and Donaldson) and nuclei (Fry). The volume is rounded off with two somewhat dated accounts of myelin and basement membranes having no full reference later than 1973, a serious drawback in these rapidly expanding fields, in which new membrane components are turning up regularly to transform previous views of membrane organisation. It is surprising too that the primary sequence of the basic protein of myelin, which was established several years ago, is nowhere discussed, particularly in connection with its encephalitogenic properties.

The most complete analysis of glycoprotein structure is in the first chapter in volume 3 by Segrest, which is particularly valuable in presenting his current views on the molecular topography of the non-polar domain of this glycoprotein. There is interesting speculation on the state of self-association of glycoprotein within the membrane and the possibilities of these aggregates in facilitating transport. One of the editors (Jamieson) provides an authoritative summary of platelet ultrastructure, perhaps the clearest case for intimate inter-relationships of the plasma membrane with underlying microtubules in a cellular function. Jamieson also summarises the intriguing evidence for collagen-platelet interactions being mediated through surface located glycosyl transferase. As Jamieson points out, some of the disagreement in this area may be due to an unwarranted extension of his original theory, concerned with simple adhesion of platelets on to collagen, to collagen-induced platelet aggregation. The membrane systems of lymphocytes and purification of their antigenic markers are then reviewed, followed by summaries of the extensive literature on tumour cells including an excellent fresh appraisal of the complex "transformation phenotype" by Paster-

nak. Volume 3 closes with three descriptive essays, respectively on the sarcoplasmic reticulum of muscle, composition and structure of excitable nerve membranes and the interactions of sperm and egg membranes in fertilization, and finally a detailed account by De Luca of vitamin A biochemistry and effects on epithelial cell membranes. The role of retinol compounds in transglycosylation is well covered.

To summarise, the series on *Mammalian Cell Membranes* is shaping up as a useful collection of articles which, despite considerable dispersal and overlap between the various volumes and rather indifferent indexing, serves a useful purpose as a source of the recent membrane literature. In one or two cases the author does more, illuminating as well as cataloguing the field. One further point: although the line drawings are in general excellent the reproduction of original photographs and electron micrographs is usually poor. In volume 2, which relies heavily on such reproductions, this is a serious drawback and is always a nuisance since often the pictures illustrate a crucial argument.

Predator-prey relationships

The Ethology of Predation. By E. Curio. Pp. x+250. (Springer: Berlin and New York, 1976.) DM72; \$29.60.

THIS is a thorough and well-presented review of a wide range of literature up to and including 1973 on the general subject of predator-prey relationships, primarily from a behavioural point of view. It will serve as a valuable reference work for many years to come. Although the main bulk of the book is concerned with behavioural aspects of predation (using the term in a very broad sense), dealing with questions of how animals detect, search for and capture food, there are brief excursions into physiological and ecological aspects of the subject. These peripheral, but important areas are dealt with in less detail than the pure behaviour, and one feels that the author is less happy with them. For example, among the ecological aspects, the discussion of the functional response contains several minor errors, such as the assertion that a type 3 response only occurs when there are at least two alternative prey types. Similarly the summary of optimal foraging theory on pages 70-80, heralded on the book cover as a link

with modern ecology, is confusing and somewhat inaccurate, and the author does not emphasise that the theory he presents at this stage applies equally to problems discussed in other parts of the book. Much of the literature on optimal foraging has appeared since 1973, so Curio's account is already dated.

Curio is, however, encyclopaedic, accurate, and critical in reviewing the more traditional ethological literature. For example, both his discussion of prey selection and the accounts of specialised hunting techniques are excellent sources of information. In the latter sections, the literature survey covers an impressive range of examples, from African natives stalking their prey under the disguise of a stuffed hornbill's head, to Green Herons hunting for fish by dropping pellets of commercial fish food into a pool at the Miami Seaquarium. My only criticism of these behavioural chapters is that the material is presented as a series of rather separate sections without a great deal of attempt to unify them. This makes this useful book more like a work of reference rather than an introduction to the subject.

John Krebs

John Krebs is Lecturer in Zoology at the Edward Grey Institute of Field Ornithology, University of Oxford, UK.

Chemisorption on evaporated films

Chemisorption: An Experimental Approach. By G. Wedler. Translated by Derek Klemperer. Pp. vi+250. (Butterworths; London and Boston, Massachusetts, 1976.) £12.

'*Quot homines, tot sententiae*', that venerable Latin tag, is particularly applicable to chemisorption. Since the recent invasion of the subject by physicists and mathematicians it has become so vast, that a full account of the simpler gases on metals alone would require a separate volume for each metal, and a chapter for each lattice plane. Therefore, it is particularly sensible that Professor Wedler, in this broad conspectus of methods, should tend to emphasise the approaches taken by his teacher, R. Suhrmann and himself, to chemisorption on evaporated metal films. This does mean, however, that a proper balance is hardly given to some of the earlier work—for example, Otto Beeck's film work is mentioned but no reference is made to J. K. Roberts' even more crucial studies on tungsten wires, which many regard as a turning point in the subject.

The index reveals no reference to accommodation coefficients or heats of adsorption on wires. Other important more modern techniques are also omitted, such as the Mossbauer effect, and neutron diffraction. The new PhD student starting up in the field would still be well advised to read the Hayward and Trapnell book (*Chemisorption*, Butterworths; London, 1964) to get the scholarly background to

the modern methods described here. But having done this, he or she will find Professor Wedler's book makes easy reading and gives a fairly wide coverage, with 744 references up to 1974. (Here a word of praise should be given to Dr Klemperer for his translation and updating of the German (1970) version.) In addition, it ends up with a short discussion of selected data on Ni/H₂ and Ni/CO, and brings Trapnell's well known Table up to date; it does, however, exclude the hydrocarbons.

Third-year undergraduates doing surface chemistry and research students will find some sections useful, but would be advised to read up nuclear and electron spin resonance elsewhere. How can one possibly explain electron spin resonance in two pages? This is a subject where *g*-factor anisotropies and hyperfine interactions (no mention of these) have contributed vital information covering the adsorbed species on oxides such as SiO₂ and MgO, and a little more effort could have given this topic its proper place in the whole picture.

Experienced workers will want to refer to it for the areas of special expertise of its author, such as electrical and heat measurements on evaporated metal films. Indeed, a better title for the book would surely have been *Chemisorption on Metals*, since there are very few references to metal oxides, or other systems apart from metals. With these qualifications, its purchase can be recommended to science libraries with an interest in the topic concerned.

D. D. Eley

D. D. Eley is Professor in the Department of Chemistry at the University of Nottingham, UK.

Our living planet

Earth, The Living Planet. By Michael J. Bradshaw. Pp. 302. (Hodder and Stoughton: London, Sydney, Auckland and Toronto, 1977.) Paperback £4.95.

THIS volume is intended as "a reader for sixth-form [advanced school] and college courses in physical geography and environmental science", and is a companion to *The Earth's Changing Surface*, about the solid Earth. *Earth, the Living Planet* divides almost equally between a description of the atmosphere, oceans, weather systems and climates of the Earth (the first half of the book) and a description of the kind of life that has evolved and adapted to those conditions. The large (A4) format, generous use of diagrams and a section of colour illustrations help to provide an attractive overall presentation, and make it easy for the reader to dip into the book for selected highlights. In a few places the need for access to the companion volume handicaps the reader who has only bought

this one of the pair; but by and large the book stands well on its own as an introduction to both the physics and the lifeforms of the biosphere.

There are, however, some deficiencies in the presentation, mostly due to over-compression of the material into a limited space. The discussion of weather modification, for example, could well have been developed further, and I was disappointed to find that the chapter "Climates of the Past—and Future?" made no mention of the Milankovitch model of Ice Ages, which in its modern form has now become widely accepted as at least a partial explanation of climatic changes on timescales of a few thousand to several tens of thousand years. By and large, the book provides an excellent introduction to our living planet, at a remarkably reasonable price, and will be useful not only as an introduction for new students but as a refresher for those whose student days are more remote.

Exploration geophysics

Applied Geophysics. By W. M. Telford, L. P. Geldart, R. E. Sheriff and D. A. Keys. Pp. xvii+860. (Cambridge University: Cambridge, London and New York, 1977.) Hardback £26; paperback £9.75.

THIS textbook of exploration geophysics is intended for practitioners and graduate students, replacing the classic works such as those of Heiland and Jakosky which are now outdated. It stems from another classic, that of Eve and Keyes published twenty years ago, but is far more than a revision of that book, reflecting two decades of particularly rapid advances in both instrumentation and interpretation. The treatment is comprehensive both in coverage of all the important geophysical techniques (developments in remote sensing seem to be the only omission) and in dealing with the practical, theoretical, geological and physical aspects of geophysics in a balanced way. The text is supplemented by problems, mostly using real data, some of which are drawn together in the last chapter to provide examples of integrated interpretation, usually in a mining context.

Over a quarter of the book is concerned with the seismic method. This section has been most successfully updated, and includes sections on the essentials of digital data processing and on the geological interpretation of seismic reflection sections. The refraction method is treated only very briefly but with a clarity which is a feature of the whole book.
